These autoimmune demyelinating polyneuropathies are considered to be immunologically mediated disorders of the peripheral nervous system.²⁵ An initial lymphocytic infiltration, and later on, an influx of macrophages, leads to demyelination. A variety of cellular and humoral immune perturbations have been described in patients with GBS. Elevated serum levels of several proinflammatory cytokines, including TNF and interferon- γ , have been reported. Other cytokines have been reported to be elevated in the spinal fluids of GBS patients, including IL-1 β and IL-6. Antibodies reactive against myelin components, e.g., ganglioside-specific antibodies such as GM₁, GD_{1b}, and GQ_{1b}, are found in the sera of many patients with GBS. Anti-GM₁ antibodies are also found in patients with motor neuropathies and motor neuron disease. Anti-GM₁ antibodies are more prominent in GBS patients lacking sensory symptoms and in those patients who have a prodromal diarrheal disease.

The association of certain viruses and bacteria, and their serologies with GBS, suggests that these microbial agents are involved in the pathogenesis of GBS. Van der Meché and colleagues²⁶ reported that the sera of GBS patients have antibodies to the ganglioside GM1 which shares epitopes on *Campylobacter* bacteria. Interestingly, the lipopolysaccharides in the capsule of *C. jejuni*, a frequent cause of diarrheal disease preceding GBS, has epitopes related to the ganglioside GM₁ and GQ_{1b}. This has led to the hypothesis of molecular mimicry in which immune responses against *C. jejuni* lipopolysaccharide produce cross-reactive antibodies to myelin with subsequent demyelination.²⁶ Another possible mechanism leading to demyelination is complement deposition on the surface of Schwann cells and the myelin sheath, which leads to the recruitment of macrophages and complement-mediated damage.

THE AUTOIMMUNE NEUROMUSCULAR JUNCTION DEFECTS

MG is an antibody-mediated autoimmune disease directed against the acetylcholine nicotinic receptor (AChR) which results in abnormalities of neuromuscular transmission leading to fluctuating weakness and fatigability (Chapter 64). A number of case reports and small, uncontrolled clinical trials have been reported, with over 100 patients undergoing treatment with IgIV.²⁴ A number of different preparations and dosage regimens have been employed. The overall response rate is about 74%, with improvement occurring within 3 weeks from the start of therapy. The duration of the response is variable and seems to be longer if patients are receiving steroids. AChR antibody titers declined in four trials but remained unchanged in three others. Overall, the clinical response did not appear to correlate with AChR antibody levels. Repeated courses of IgIV may be needed to maintain improvement. A recent controlled trial

THERAPEUTIC PRINCIPLES

TREATMENT EFFICACY IN PATIENTS WITH AUTOIMMUNE NEUROMUSCULAR DISEASES

Proven efficacy

Guillain-Barré syndrome
Chronic demyelinating polyneuropathy
Multifocal motor neuropathy
Dermatomyositis (adults)

Probable treatment efficacy

Myasthenia gravis
Stiff-person syndrome
Multiple sclerosis, relapsing remitting disease

Possible treatment efficacy

Childhood epilepsies
>> West syndrome
>> Lennox-Gastaut syndrome
Obsessive-compulsive disorder (Tourette syndrome)

KEY CONCEPTS

THE IMMUNE PATHOGENESIS OF GUILLAIN-BARRÉ SYNDROME AND CHRONIC INFLAMMATORY DEMYELINATING POLYNEUROPATHY

- >> Molecular mimicry between epitopes on capsule of *Campylobacter jejuni* and myelin
 - Preceding history of diarrhea
 - Positive stool culture for *C. jejuni*
- >> Autoantibodies to myelin components, i.e., ganglioside-specific antibodies (GM1, GD_{1b}, GQ_{1b})
- >> Macrophage influx into lesions
- >> Complement deposition on Schwann cell and myelin sheath

comparing the efficacy and side effects of IgIV to plasma exchange in MG patients undergoing exacerbation, using two IgIV dosages, showed similar efficacy, but fewer side effects in the IgIV group.²⁷

THE INFLAMMATORY MYOPATHIES

Polymyositis, DM, and inclusion-body myositis are inflammatory muscle disorders characterized by muscle weakness and cellular infiltrates within the skeletal muscles (Chapter 56). Although the pathogenesis of these diseases is thought to be similar, each inflammatory myopathy group has characteristic clinical and immunopathologic features that sets each apart. DM affects the proximal muscles and is associated with a violaceous rash on the face and extremities.

Dalakas and coworkers²⁸ conducted a double-blind, placebo-controlled study of 15 patients (age 18–55 years) with treatment-resistant DM. Patients were randomly assigned to receive IgIV therapy (2 g/kg) or placebo every month for 3 months. The patients receiving IgIV had significant improvements in muscle strength, neuromuscular symptoms related to daily living, and skin rash. Clinical improvement became noticeable about 15 days after the first IgIV infusion. Serum creatine kinase fell by 50% after the first infusion, with further decreases toward normalization in subsequent infusions. Unfortunately, continued improvement of these patients was variable. Some patients continued to get IgIV less frequently and were able to maintain improvement along with low-dose steroids. Some patients who were unresponsive to steroids during their initial treatment regimen became steroid-responsive following IgIV infusion.

Muscle biopsy studies showed marked improvement in muscle histology after IgIV treatment.²⁹ The mean muscle fiber diameter and the mean number of capillaries increased. Immunological activation markers, such as major histocompatibility complex class I determinants and ICAM-1 expression, became diminished after IgIV therapy. Transforming growth factor- β (TGF- β), which is upregulated in the muscle tissues of patients with DM, was markedly downregulated. Finally, in muscle biopsies after therapy, the complement-mediated damage was diminished after IgIV therapy.²⁹

Inclusion-body myositis is the most common inflammatory muscle disorder in individuals above the age of 50 and is characterized by a slowly progressive muscle weakness and atrophy affecting the proximal and distal muscle groups. Dysphagia is also frequent, occurring in 60% of patients. Initial open-label small trials suggested that IgIV was helpful in some patients with inclusion-body myositis, particularly with activities related to daily living. Other uncontrolled studies showed no benefit of IgIV. A double-blind, placebo-controlled cross-over study in 19 patients with inclusion-body myositis using monthly IgIV infusions of 2 g/kg or placebo for 3 months showed a mild statistical improvement in the IgIV group (6 of 19 patients); the study did not establish efficacy for IgIV treatment. In a follow-up study, combining IgIV therapy with prednisone, there appeared to be no clear benefit. However, some patients may have some transient benefit from IgIV therapy, especially those with severe dysphagia.^{21, 29}

THE CENTRAL NERVOUS SYSTEM DISEASES

Multiple sclerosis is the most common demyelinating disorder of the central nervous system, and studies have suggested that the pathogenesis of multiple sclerosis is related to an autoimmune process (Chapter 65). Several uncontrolled and open-label studies have shown a beneficial effect of long-term IgIV therapy in the treatment of acute exacerbations in patients with multiple sclerosis.³⁰ In a randomized placebo-controlled trial of monthly infusions of IgIV (0.15–0.2 g/kg) therapy in patients with relapsing remitting multiple sclerosis, the number of patients who improved in the IgIV group was 31%, while in the placebo group only 14% of patients improved. Side effects were minimal. Other studies correlated changes in disease activity with changes in multiple sclerosis lesions, as measured by magnetic resonance imaging. A meta-analysis of four controlled trials in patients with relapsing remitting MS showed that IgIV significantly reduced the annual relapse rate, increased the proportion of relapse-free patients, and reduced disease progression, as measured by the change in Kurtzke expanded disability status scale.³⁰

Stiff-person syndrome is characterized by fluctuating muscle rigidity, episodic muscle spasms, and high titers of antibodies against glutamic acid decarboxylase. In a placebo-controlled cross-over trial by Dalakas^{21, 29} of 16 patients treated with 2 g/kg of IgIV or placebo for 3 months, stiffness scores decreased, heightened sensitivity scores declined, and patients were able to walk and perform work-related or household tasks.

Ten to 20% of childhood epilepsies are intractable, i.e., not controlled adequately with first-line conventional anti-epileptic drug therapy. Children with epilepsy, who were treated with IgIV for recurrent respiratory tract infections, had a decrease in the frequency and severity of their seizures. A number of investigators have suggested that immune mechanisms are important in the pathogenesis of epilepsy, particularly those that are associated with infections or vaccination. A number of reports have appeared on the responsiveness of certain patients with childhood epilepsy to IgIV therapy. The favorable effects of IgIV treatment were especially seen in children with variant forms of epilepsy, such as West syndrome and Lennox-Gastaut syndrome. Placebo-controlled studies showed significant reductions in seizure episodes with IgIV treatment. Additional multicenter placebo-controlled trials are needed to define further the subpopulation of children with intractable seizures who would benefit from IgIV treatment, although the best candidates appear to be those patients with West syndrome and Lennox-Gastaut syndrome and those patients who have postinfectious epileptic encephalopathies. Perlmutter and coworkers³¹ reported a placebo-controlled study with plasma exchange and IgIV in patients with obsessive-compulsive disorder and tic disorders (Tourette syndrome). At 1 month the plasma exchange and IgIV groups showed striking improvements on several neuropsychiatric functioning scales. Tic symptoms also significantly improved. Improvement was maintained at 1 year by 82% of the children in both the plasma exchange and IgIV groups.

MECHANISMS OF ACTION OF IgIV IN NEUROMUSCULAR DISEASES

The autoimmune neurologic diseases and inflammatory myopathies provide a broad group of immunologically mediated diseases in which many inflammatory and immune-mediated effector pathways lead to tissue destruction. These neurological and myopathic diseases provide models for the study of the mechanisms of action by which IgIV modulates these autoimmune and inflammatory processes. Several mechanisms have been proposed for the immune-modulating effects of IgIV. IgIV may modulate the inflammatory response by the suppression of cytokine production. Proinflammatory cytokines, e.g., TNF- α and IL-1 β , in GBS patients decrease with IgIV therapy. Dalakas²⁹ documented reduction in muscle levels of ICAM-1, TGF- β , and TGF- β mRNA in patients with inflammatory myopathies after IgIV treatment. Although IgIV may contain antibodies to certain cytokines, other studies suggested that IgIV was downregulating cytokine production by inhibiting gene expression. Of interest, plasma exchange was not associated with a decrease in these proinflammatory cytokines, suggesting that the mechanisms of action of plasma exchange and IgIV in GBS may be quite different.

A number of studies have shown that IgIV contains antibodies with idiotypic specificities that can bind and neutralize potentially pathogenic autoantibodies such as anti-GM1 antibodies in GBS and CIDP and anti-AchR in MG.²⁹ Malik and coworkers³² showed that anti-idiotypic antibodies in the IgIV directed against idiotopes located on the anti-GM1 immunoglobulin molecule blocked the binding of the

anti-GM1 antibodies to its target antigen. Van Doorn et al.,³³ using an immunofluorescence assay, showed that the sera of patients with GBS and CIDP contained antibodies to a cell membrane constituent of a neuroblastoma cell line. Intact IgIV or F(ab')₂ fragments blocked these antibodies from binding to the cell membrane of this neuroblastoma cell line. These studies again suggest an idiotype-anti-idiotype interaction as a possible mechanism by which IgIV could modulate the immune-mediated disease process and contribute to remyelination in patients with GBS and CIDP. Support for a similar mechanism in MG comes from the fact that IgG or F(ab')₂ fragments in the IgIV preparations are capable of binding to AChR antibodies *in vitro*.³⁴ Using *in vitro* nerve muscle preparations, Buchwald et al.³⁵ showed that the F(ab')₂ portion of IgIV neutralized the 'blocking' effect of serum from patients with acute GBS.

As discussed above for ITP, the administration of large amounts of IgG could saturate the FcRn receptor and accelerate the degradation of the IgG autoantibodies found in many of the autoimmune neuropathies. This mechanism may be applicable to antibody-mediated neuromuscular diseases such as MG, Lambert-Eaton myasthenia syndrome, GBS, stiff-person syndrome, CIDP, and multifocal motor neuropathy.

The principal inflammatory mechanism in DM is complement (C)-dependent microangiopathy with activation of C3 and deposition of the complement C5b-9 membranolytic attack complex (MAC) on the endomysial capillaries.²⁹ Basta³⁶ has shown that IgIV can inhibit the uptake of C components on target tissues. In DM patients treated with IgIV, C3 deposition was reduced, with corresponding decreases in MAC expression on endomysial capillaries.^{29, 36} IgIV prevents the uptake of complement components and formation of the MAC on the endomysial capillaries in the muscle tissues of patients with DM. Consequently, IgIV allowed neovascularization to occur and reversal of the ischemic process, resulting in muscle tissue healing. This effect of IgIV on complement deposition may be relevant to other autoimmune neurological diseases, such as MG, in which complement may be playing a role in the tissue damage at the postsynaptic junctional membrane.^{29, 36}

CONNECTIVE TISSUE DISORDERS

SYSTEMIC VASCULITIS

IgIV has been shown to be useful as adjunct therapy in patients with anti-neutrophil cytoplasmic antibody (ANCA)-positive systemic vasculitis (Chapter 59). High-dose IgIV (e.g., 400 mg/kg per dose given over 5 consecutive days) may benefit the disease activity and circulating ANCA levels. ANCA levels decreased by 51% of pretreatment values, and improvement started 2 days to 3 weeks after IgIV therapy; 5 patients went into full remission. Other investigators also reported beneficial clinical responses following high-dose IgIV treatment. Response rates vary between 60% and 100%, and may be related in some patients to a chronic parvovirus B19 infection. Further placebo-controlled studies are needed.

RHEUMATIC DISEASES

The clinical studies of IgIV therapy in patients with rheumatoid arthritis (Chapter 52) and systemic lupus erythematosus (SLE) (Chapter 51) have been case reports and open-labeled studies.² Most have shown little

KEY CONCEPTS

MECHANISMS OF ACTION OF INTRAVENOUS IMMUNOGLOBULIN IN NEUROMUSCULAR DISEASES

- >> Modulation of proinflammatory cytokines, e.g., tumor necrosis factor- α , interleukin-1 β in Guillain-Barré syndrome
- >> Reduction in muscle levels of ICAM-1, transforming growth factor (TGF)- β and TGF- β mRNA in dermatomyositis
- >> Neutralize potentially pathogenic autoantibodies, e.g. anti-Gm1 antibodies in Guillain-Barré syndrome and chronic inflammatory demyelinating polyneuropathy, and anti-acetylcholine nicotinic receptor in myasthenia gravis
- >> Intravenous immunoglobulin saturate neonatal Fc receptors to accelerate degradation of immunoglobulin G autoantibodies
- >> Inhibit complement deposition and formation of membranolytic attack complex on endomysial capillaries in dermatomyositis

or no efficacy, with a potential for worsening or exacerbation of the renal disease in SLE patients.

Mechanisms of action of IgIV in rheumatic diseases and vasculitides

A number of mechanisms of action have been proposed to explain the immunoregulatory effects of IgIV in patients with vasculitis. Immune complexes are felt to be a major component in the pathophysiology of these inflammatory diseases. Several studies have suggested that IgIV can solubilize immune complexes, making them less nephritogenic. This is supported by the observations of decreases in circulating immune complexes in SLE patients treated with IgIV.

Commercial IgIV contains anti-idiotypic anti-DNA antibodies that are capable of blocking the combining sites of IgG anti-DNA antibodies. IgIV also contains anti-idiotypic antibodies against a number of autoantibodies such as anti-DNA, anti-factor VIII, ANCA autoantibodies, anti-thyroid autoantibodies, and others.³⁷ The proposed mechanism of action of IgIV in ANCA-positive vasculitis is binding or neutralization of the ANCA autoantibodies by anti-idiotypic antibodies in the IgIV. These anti-idiotypic antibodies may also act in concert with their effects on the Fc γ RIIB receptor on B cells to produce a negative 'off signal' to the B cells synthesizing these autoimmune antibodies.³⁸ Thus, the anti-idiotypic antibodies in IgIV may be beneficial by restoring the idiotypic control network in these autoimmune diseases.

ANTI-PHOSPHOLIPID ANTIBODY SYNDROME AND RECURRENT SPONTANEOUS ABORTION

Another related disorder to SLE in which IgIV has been used as treatment is the anti-phospholipid antibody syndrome, which is associated with recurrent spontaneous abortion (RSA) (Chapter 61). In this condition autoantibodies are present to certain phospholipids such as cardiolipin. Clinical manifestations include a thrombotic diathesis often associated

with recurrent fetal loss or fetal wastage that is considered to be secondary to placental infarcts, resulting in placental insufficiency. RSA, defined as two or more consecutive pregnancy losses before 20 weeks of gestation, occurs in approximately 5% of couples. Laboratory tests in these patients include false-positive tests for syphilis (Venereal Disease Research Laboratory), and the presence of a lupus anti-coagulant (LAC). Therapy with corticosteroids, low-dose aspirin, and heparin has been directed at suppressing the production of these autoantibodies and controlling the thrombotic diathesis. Several randomized controlled trials of IgIV therapy in Europe, Canada, and the USA have been completed using dosages ranging from 25g to 30 g biweekly or 500 mg/kg monthly from early pregnancy to 28–32 weeks' gestation. Daya et al.³⁹ performed a meta-analysis of four randomized double-blind placebo-controlled trials of IgIV in women with RSA. Two studies showed an increase in successful pregnancy outcome with IgIV treatment, whereas two other studies did not show positive results.³⁹ The overall odds ratio of these four studies was 1.48 in favor of IgIV, with a treatment effect of approximately 10%. A recent meta-analysis of placebo-controlled studies suggests that there is little or no benefit from IgIV treatment in patients with RSA.⁴⁰

ANTIBODY-MEDIATED REJECTION

Antibody-mediated organ rejection (AMR) of organ grafts is a significant and unique form of graft rejection that does not respond well to standard immunosuppressive therapy directed at T-cell responses (Chapter 80). AMR is particularly a problem in those patients who are highly human leukocyte antigen (HLA)-sensitized or have ABO-incompatible transplants. Anti-HLA (donor-specific) antibodies and anti-endothelial cell antibodies are often associated with AMR. Rapid onset of allograft dysfunction in a high-risk patient may indicate AMR, and is characterized by C4d deposition in the peritubular capillaries. IgG complement-fixing antibody to donor HLA antigens or IgG-positive T-cell cross-match indicates a high risk for AMR. Jordan and colleagues⁴¹ have shown that pretreatment with high-dose IgIV decreases anti-HLA donor-specific antibodies, and is an effective treatment for AMR episodes.

TOXIC SHOCK SYNDROME

A clinical area where IgIV may have therapeutic value is in the treatment of patients with toxic shock syndrome secondary to *Staphylococcus aureus* or *Streptococcus pyogenes* exotoxins. In an open study by the Canadian Streptococcal Study Group,⁴² IgIV appeared to be beneficial in patients with streptococcal toxic shock syndrome. In a meta-analysis of IgIV treatment of neonatal sepsis there was a sixfold decrease in mortality.⁴³ IgIV inhibits *Staphylococcus* exotoxin-induced T-cell activation, and contains antibodies against exotoxins responsible for toxic shock syndromes. Great variations in neutralizing activity against streptococcal pyrogenic exotoxins of different brands and even among different lots of IgIV can be found. However, these findings suggest that it is possible to select one IgIV preparation that contains high levels of neutralizing activity against a wide variety of group A streptococcal superantigens, which could be used in the treatment of streptococcal toxic shock syndrome. The neutralizing capacity of IgIV for these bacterial superantigens is important because of their potential to stimulate the production of proinflammatory cytokines that lead to clinical disease.

INFLAMMATORY AND AUTOIMMUNE SKIN DISEASES

TOXIC EPIDERMAL NECROLYSIS AND STEVENS–JOHNSON SYNDROME

Toxic epidermal necrolysis (TEN) and Stevens–Johnson Syndrome (SJS) are severe drug-induced skin diseases (reviewed in Letko et al.⁴⁴) (Chapter 48). TEN results in apoptotic epidermal cell death in which there is separation of large areas of the skin at the epidermal junction, producing the appearance of scalded skin. Keratinocyte apoptosis that precedes epidermal detachment is an early event in TEN. A number of drugs can cause TEN and SJS, including sulfonamides, anticonvulsants, and nonsteroidal anti-inflammatory medications. The mortality rate can be as high as 30%. Viard et al.⁴⁵ studied serum samples from patients who had TEN and found that the serum of these patients had very high levels of soluble Fas ligand (sFasL). Keratinocytes normally express the death receptor Fas. The keratinocytes of patients with TEN also express very high levels of active Fas ligand. In a small pilot study, Viard and coworkers⁴⁵ administered IgIV (0.2–0.75 g/kg for 4 consecutive days) to 10 patients with TEN. In all 10 patients, the progression of skin disease was rapidly interrupted within 24–48 hours with rapid skin healing and no adverse effects. In *in vitro* studies, IgIV was added to keratinocyte cell cultures to determine whether IgIV could interfere with Fas-mediated cell death. IgIV completely inhibited Fas-mediated keratinocyte apoptosis. This effect was related to the presence of Fas-blocking antibodies in the IgIV. Thus, the mechanisms by which IgIV leads to clinical improvement in patients with TEN is likely related to the inhibition of Fas-mediated keratinocyte cell death by naturally occurring Fas-blocking antibodies in the IgIV preparation. Faye and Roujeau⁴⁶ examined nine studies (156 patients) in which high-dose IgIV was used in the treatment of TEN and SJS. Variations in dosages, time to initiation of therapy, and duration of therapy precluded a meta-analysis. These authors concluded that, although IgIV may be beneficial in TEN and SJS, the effects may be small. Any firm conclusions will have to await randomized placebo-controlled trials. Nevertheless, this mechanism of action of IgIV may be useful in other diseases, in which tissue injury is mediated by Fas-mediated apoptosis.

AUTOIMMUNE MUCOCUTANEOUS BLISTERING DISEASES

Autoimmune mucocutaneous blistering diseases are a group of diseases, e.g., pemphigus foliaceus, pemphigus vulgaris, bullous pemphigoid, mucous membrane pemphigoid, epidermolysis bullosa acquisita, that involve the skin and mucous membranes and that are immunologically mediated, most often by tissue-specific antibodies (Chapter 63). These diseases are treated with high-dose systemic steroids and immunosuppressive agents. A more detailed description of the clinical presentation, pathogenesis and immunology of these diseases can be found elsewhere (Chapter 63). There is now a growing literature on the use of high-dose IgIV therapy in patients with autoimmune blistering disease.⁴⁷ The mechanisms of action of IgIV in autoimmune blistering diseases are probably similar to the mechanisms described above for ITP and the autoimmune neurological diseases. For example, in pemphigus the antibodies decreased by 70% 1 week after a single treatment of IgIV; Li

KEY CONCEPTS

MECHANISMS OF ACTION OF INTRAVENOUS IMMUNOGLOBULIN IN INFLAMMATORY AND AUTOIMMUNE SKIN DISEASES

- >> Fas antibodies in intravenous immunoglobulin inhibit Fas-mediated keratinocyte apoptosis in toxic epidermal necrolysis
- >> Anti-idiotypic neutralization of autoimmune antibodies in autoimmune mucocutaneous blistering diseases
- >> Enhanced degradation of autoantibodies through the neonatal Fc receptor pathway
- >> Inhibit cytokine production
- >> Inhibit B-cell function and decreased autoantibody production through activation of the FcγRIIB receptor (signaling through the immunoreceptor tyrosine-based inhibition motif (ITIM))

et al.⁴⁸ reported that the therapeutic efficacy of IgIV was dependent on the FcRn pathway of antibody catabolism. Often concomitant therapy with steroids or other immunosuppressive drugs can be reduced or even discontinued. However, like other autoimmune disorders, the response to IgIV can be variable. In two other studies of pemphigus vulgaris and pemphigus foliaceus patients were disease-free by approximately 5 months of monthly infusions of IgIV.⁴⁹ Immunosuppressive therapy was reduced or discontinued on average after 18–19 cycles of IgIV over 27–30 months. However, controlled studies remain to be done. Further discussions on the use of IgIV for autoimmune blistering disease can be found elsewhere.⁵⁰

IgIV IN ATOPIC DISEASES

Asthma

A number of advances and new drugs have been introduced over the past 10 years for the treatment of asthma (Chapter 40). Nevertheless, a subset of asthmatic patients continues to have frequent exacerbations of asthma, requiring high doses of inhaled corticosteroids or oral systemic steroids to control their asthma. In an open-label study of IgIV (2 g/kg at monthly intervals) in 8 children (ages 6–17) who had severe steroid-dependent asthma, the average alternate-day steroid dose decreased with improvements in peak flow rates and symptom scores. The serum IgE levels decreased from 324 IU prior to therapy to 133 IU after 6 months on IgIV. Of interest, immediate hypersensitivity skin testing to inhalant allergens decreased by 100-fold. Several other preliminary clinical trials suggested that IgIV was helpful in severe corticosteroid-dependent asthmatics, in whom the IgIV had a steroid-sparing effect. These clinical observations prompted other investigators to initiate randomized double-blind placebo-controlled multicenter studies. In a multicenter randomized placebo-controlled study⁵¹ of high-dose IgIV in oral corticosteroid-dependent asthmatics with two IgIV treatment groups, e.g., 1 and 2 g/kg at monthly intervals for 7 months, no differences were observed between

FOOD AND DRUG ADMINISTRATION-APPROVED INDICATIONS FOR INTRAVENOUS IMMUNOGLOBULIN

- >> Patients with primary immunodeficiency disease – replacement therapy
- >> Idiopathic thrombocytopenia – prevent severe bleeding
- >> Children with human immunodeficiency virus (HIV)/acquired immunodeficiency syndrome (AIDS) and recurrent infections – prevent serious bacterial infections
- >> B-cell chronic lymphocytic leukemia with recurrent infections and humoral immune deficiency – prevent bacterial infection
- >> Kawasaki disease – to prevent coronary artery aneurysms
- >> Bone marrow transplantation – decrease risk of infection, interstitial pneumonia, and graft-versus-host disease in the first 100 days after transplantation

the placebo (albumin 2 g/kg per month) and the two IgIV treatment groups for forced expiratory volume in 1 second, emergency room visits, or days missed from work or school. Adverse events were common in the IgIV groups, especially in the high-dose treatment group. In another double-blind placebo-controlled randomized trial of IgIV in children with severe asthma, there was a significant reduction in oral steroid requirement in both the IgIV and placebo treatment groups.⁵² In a subgroup of patients requiring extremely high doses of oral steroids (> 2000 mg in the year before the study), there was a significant steroid-sparing effect by the IgIV. These authors concluded that IgIV was useful in a subgroup of severe asthmatic patients who required high doses of oral steroids. A larger placebo-controlled trial is needed to determine the efficacy of IgIV therapy in oral steroid-dependent asthmatics.

A number of mechanisms have been proposed for the effects of IgIV in asthma. Several studies have shown that IgIV can modulate the synthesis of cytokines. Related to cytokine inhibition, Spahn et al.⁵³ showed that the addition of IgIV to phytohemagglutinin (PHA)-stimulated lymphocytes shifted the dexamethasone dose-response curve, rendering the cells more sensitive to the suppressive effects of steroids in patients with glucocorticoid-insensitive asthma. In addition, IgIV significantly improved glucocorticoid receptor-binding affinity that may be responsible for the steroid-sparing effects of IgIV.

The mechanism(s) by which IgIV suppresses immunoglobulin synthesis by B cells has been postulated to occur by inhibiting cytokine production and by directly suppressing B-cell function through its low-affinity Fcγ receptor. The FcγRIIB receptor on B cells can provide a negative signal through protein tyrosine phosphatases (SHP-1) to inhibit B-cell proliferation and decrease antibody synthesis. The mechanism for this negative signaling in B cells is thought to occur by the immunoreceptor tyrosine-based inhibition motif (ITIM) that is known to be associated with the intracytoplasmic domain of the FcγRIIB receptor. Co-ligation of the B-cell receptor and the FcγRIIB receptor could occur by the binding of IgG in IgIV through its Fc moiety to the FcγRIIB receptor and the F(ab')₂ moiety with anti-idiotypic antibody specificity to the B-cell

antigen receptor. Thus, through pathways that modulate cytokine production and decrease B-cell Ig synthesis, i.e., diminished serum levels of IgE antibodies, IgIV may have both anti-inflammatory and immunomodulating effects in the immunopathogenesis of asthma.

Chronic urticaria

A subset of patients with chronic urticaria (Chapter 42) have IgG autoantibodies directed against the α-chain of the high-affinity receptor for IgE, suggesting an autoimmune etiology. In 10 patients with chronic severe urticaria poorly responsive to conventional therapy, treatment with IgIV (0.4 g/kg per day for 5 days) showed clinical benefit in 9 patients, including 3 who had prolonged remission over a 3-year follow-up period. The majority of responders had a decreased wheal-and-flare response to intradermal autologous serum compared with their pre-IgIV response. Placebo-controlled studies are needed.

CONCLUSIONS

IgIV has been found to be an effective treatment for a wide spectrum of autoimmune and inflammatory diseases. At present, IgIV is FDA-approved for only a few autoimmune and inflammatory diseases, e.g., ITP and KS. However, even in ITP and KS, the mechanism of action of IgIV remains to be fully elucidated. Although no single mechanism can explain the beneficial effects of IgIV, it is likely that several mechanisms of action working together are responsible for the effects of IgIV in the many clinical disorders for which it has been used. It is important to recognize that IgIV contains not only a broad spectrum of IgG antibodies, but also small amounts of other immunoglobulin isotypes, as well as soluble cell membrane products and HLA determinants. These “contaminants” may in fact play an important immunomodulatory role in autoimmune and inflammatory diseases. A better understanding of the pathogenic mechanisms involved in these diseases will undoubtedly lead to more effective therapy with IgIV or more specific, modified forms of this product.

Gene transfer therapy of immunologic diseases

Javier Chinen, Fabio Candotti

86

Immunodeficiency diseases comprise a group of clinical conditions characterized by an impairment of one or more components of the immune system, resulting in increased susceptibility to infections and, in some particular diseases, to an increased incidence of neoplastic and autoimmune disorders. According to their etiology, immunodeficiencies can be classified into two major categories: primary and secondary. Primary immunodeficiencies result from inherited or 'de novo' defects in genes encoding proteins that are involved in the development and function of the cells of the immune system. Secondary immunodeficiencies are acquired disorders caused by environmental agents (e.g., infectious agents, radiation, immunosuppressive drugs), or by processes that indirectly affect the immune system, such as malnutrition. Currently, infection by the human immunodeficiency virus (HIV) is the most common form of immunodeficiency found in clinical practice in developed countries. HIV infects and causes the death of CD4 T cells, progressively reducing the ability of the infected individual to activate and develop immune responses. Both primary and secondary immunodeficiencies represent a management challenge for the clinician, who has a limited number of treatment options for these diseases: reversal of most severe primary immunodeficiencies today requires hematopoietic stem cell transplantation (HSCT), and most HIV-infected individuals will require anti-retroviral therapy. However, HSCT has significant mortality and side effects. Also, anti-HIV therapy halts disease progression but seldom eradicates the virus, necessitating lifelong treatment that can be associated with severe adverse effects and the development of anti-retroviral drug resistance.

In the mid 1980s, gene therapy was proposed as an alternative treatment to genetic diseases, including inherited immunodeficiencies with known genetic defects (Table 86.1). Applications of gene therapy strategies were suggested for a wide variety of conditions, including treatment of cancer and HIV infection. In 2006 there were 119 active gene therapy clinical protocols in the USA, 72 of which were directed to the treatment of cancer using genes expected to stimulate the immune response and therefore help to eliminate cancer cells.¹ Five of the studies were proposed

for genetic intervention in HIV infection, and five other protocols were directed to gene correction of monogenic diseases. Two of these were designed for primary immunodeficiencies: X-linked severe combined immunodeficiency (XSCID) and adenosine deaminase (ADA) deficiency. The remaining studies tested the safety and efficacy of approaches for the genetic modification of bone marrow cells using nontherapeutic genes.

In this chapter, we review in chronological order the progress achieved in the development of gene therapy for primary immunodeficiencies and for the control of HIV infection, with a focus on its application to the clinical management of affected patients.

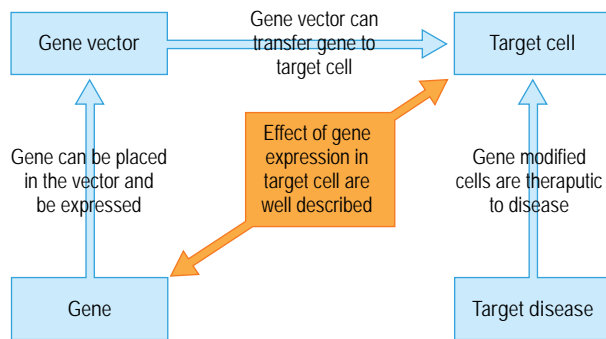

■ GENE THERAPY AS TREATMENT MODALITY ■

Gene therapy can be described as a therapeutic strategy that involves the genetic modification of a target cell in order to produce biological effects that halt or reverse a disease process. Investigators need to carefully consider at least four aspects of any gene therapy approach: the pathogenesis of the disease; the target cell intended to modify; the therapeutic gene to be used; and the vector to transfer the therapeutic gene into the target gene (Fig. 86.1).

Several viral and nonviral methods have been reported for gene therapy (Table 86.2). Retroviral vectors derived from murine leukemia virus have been the preferred gene vectors for immunodeficiencies, because of their ability to integrate permanently into the genome of the target cells, which is a prerequisite for long-term correction of genetic diseases. The integrated provirus behaves as a gene transcription unit, with the therapeutic gene copied into daughter cells during cell replication. The gene therapy field has accumulated extensive experience with gene transfer of hematopoietic stem cell (HSC) using these vectors (Fig. 86.2). Significant limitations of murine retroviral vectors are the need for cell division for efficient gene transfer, and recent reports of retroviral insertional oncogenesis in animal

Table 86.1 Primary immunodeficiency candidates for gene therapy

	Gene	Gene regulation required	Correction of animal model	<i>In vitro</i> human cell correction	Clinical trial
ADA deficiency	<i>ADA</i>	No	Yes	Yes	Successful
CGD (X-linked)	<i>gp91phox</i>	No	Yes	Yes	Successful
CGD (autosomal)	<i>p47phox</i>	No	Yes	Yes	Unsuccessful
LAD type I	<i>CD18</i>	No	Yes	Yes	Unsuccessful (two patients treated)
XSCID	<i>IL2RG</i>	No	Yes	Yes	Successful
JAK3-SCID	<i>JAK3</i>	No	Yes	Yes	Unsuccessful (one patient treated)
Hyper IgM type 1	<i>CD40L</i>	Yes	Yes, induced lymphoma	Yes	None
Wiskott–Aldrich syndrome	<i>WASP</i>	No	Yes	Yes	None
X-linked agammaglobulinemia	<i>BTK</i>	Yes	Yes	Not reported	None
RAG1/2 deficiency	<i>RAG 1/2</i>	Yes	Yes, induced lymphoma	Not reported	None
IL7RA deficiency	<i>IL7RA</i>	Yes	Yes	Yes	None
Artemis-SCID	<i>DCLREC1</i>	Yes	Yes	No	None

models and humans. However, there is an active development of alternative vectors, for example based on mammalian lentiviruses and foamy viruses. Other efforts are aimed at developing retroviral vectors using viral envelopes with increased efficiency to transduce HSCs.²

GENE THERAPY FOR PRIMARY IMMUNODEFICIENCIES

More than 120 genetic defects are known to cause primary immunodeficiency (PI) disorders. The most common PIs are characterized by defective antibody responses, albeit with relatively intact cellular immunity. Patients with these conditions are usually treated with

immunoglobulin replacement and achieve an acceptable reduction of the frequency of infections. In contrast, immunodeficiencies associated with defective T-cell function, e.g., SCID, are almost always fatal unless treatment to restore immune function is provided. Currently, the standard curative therapy for many types of SCID and other severe PIs is hematopoietic stem cell transplantation (HSCT).³ In addition, enzyme replacement is available for patients with genetic defects of ADA.⁴ Weekly intramuscular injections of bovine ADA enzyme conjugated to polyethylene glycol (PEG-ADA) improve immune function in most of these patients, but requires continuous administration. HSCT treatment performed in an experienced medical center can rescue up to 75–90% of infants diagnosed with SCID, obtaining the best results if performed in the first 3 months of life, before devastating infections occur.³ If HSCT is performed using an

Wild type murine retrovirus

Retrovirus Vector

transfected into
packaging cell

Fig. 86.2 Structure of a typical retroviral vector. Structural retroviral genes are removed from the wild-type retrovirus, which leaves space to insert the gene of interest. Long terminal repeats (LTRs) and packaging signal (ψ) are elements necessary for viral replication. Packaging cells provide the viral capsid and envelope proteins that are necessary to form a complete viral particle able to infect target cells and integrate its genome into the genomic DNA.

2004	Additional gene therapy trials for XSCID and ADA-SCID confirms the efficacy of this experimental treatment
2006	Gene therapy for two CGD patients restored microbicidal capacity of neutrophils and helped clear chronic infections

ADA, adenosine deaminase; XSCID, X-linked severe combined immunodeficiency; CGD, chronic granulomatous disease.

HLA-matched sibling as a donor, the rate of immune reconstitution reaches over 90%. Because of the infrequent availability of a HLA-matched related donor; however, HSCT is usually performed from a haploidentical HLA (parental) donor, which results in a lower probability of success and an increased risk for morbidity and mortality over time. A significant number of patients treated with haploidentical HSCT may achieve only partial or unstable immune reconstitution. Others suffer acute or chronic graft-versus-host disease (GvHD) and, if a myeloablative conditioning regimen is used, side effects due to chemotherapy.

Because of the severity of the clinical phenotype, the infrequent availability of HLA-identical sibling donors and the imperfect results of HSCT, gene therapy has been investigated as an alternative treatment for primary immunodeficiencies, aiming at the correction of gene defects in hematopoietic stem cells (HSC). PIs have played a major role in the development of gene therapy since the inception of this novel area of medicine. (Table 86.3) In the mid 1980s ADA deficiency was identified as one ideal candidate disease, and soon thereafter became the first disease to be treated in an NIH-approved clinical gene therapy trial.³ Thereafter, preclinical and clinical trials of corrective gene transfer for PIs have advanced the gene therapy field and have reported clear therapeutic successes, as well as the serious adverse events that occurred in a clinical trial for XSCID, described below.

GENE THERAPY FOR ADA-SCID

Genetic mutations affecting ADA function result in a heterogeneous presentation of immunodeficiency characterized, in severe cases, by profoundly reduced numbers of T and B cells and a consequent lack of both cellular and humoral responses (Chapter 35). ADA is an enzyme present in every cell in the body, but its deficiency primarily affects lymphocytes because the purine intermediates that build up in the absence of ADA are particularly toxic to B and T cells. Allogeneic HSCT and enzyme replacement therapy have proved life-saving for affected patients.^{3,4} Gene therapy approaches have been developed to improve on the toxicity and limited efficacy that complicate these existing forms of treatment. Recent milestones in the treatment of ADA deficiency are described below.

As mentioned above, ADA deficiency was the first genetic disorder in which the 'proof of concept' of gene therapy was demonstrated. In 1990, two ADA-deficient girls were enrolled in the first single-gene disease clinical trial at the National Institutes of Health.⁵ Peripheral blood T cells were obtained by apheresis, expanded *ex vivo* in IL-2-containing media, transduced with a retroviral vector carrying the ADA cDNA, and infused back into the patients. Over a 2-year period the two patients received a series of 11–12 infusions of *in vitro* expanded gene-corrected cells. Clinical follow-up showed a prolonged increase in T-cell numbers, the development of antigen-induced cutaneous delayed-type hypersensitivity, and normalization of isohemagglutinins

KEY CONCEPTS

GENE THERAPY FOR ADA DEFICIENCY

- >> The 'proof of concept' of gene therapy was first demonstrated in a clinical trial involving two patients with ADA deficiency who received autologous gene-modified T cells.
- >> The routine use of replacement enzyme, PEG-ADA, might reduce survival advantage for ADA gene-corrected lymphocytes.
- >> Successful immunologic reconstitution has been obtained with ADA gene therapy to bone marrow HSCs, with nonmyeloablative conditioning and in the absence of PEG-ADA.
- >> Reported side effects in this trial were secondary to cytoreductive therapy, including transient myelosuppression.

titers and antibody responses to vaccines. In patient 1, more than 50% of circulating peripheral blood lymphocytes carried the corrected ADA gene, resulting in measurable ADA activity of nearly 25% of normal levels. Patient 2 showed very low numbers of transduced cells (0.1–1%) and barely detectable ADA enzyme expression. One possible explanation for the different outcomes in the two patients is the development of an immune response in patient 2 against the fetal calf serum used during the *in vitro* gene transfer procedure. T cell-directed gene therapy was also used in the treatment of an ADA-deficient patient in Japan, starting in 1995. Improvements in T-cell numbers and function were observed in this patient, with gene correction of over 15% of circulating lymphocytes and good levels of ADA enzyme activity.⁶

The results of T-cell gene therapy for ADA deficiency were encouraging, with the observation of a series of immune responses that were absent or barely detectable before the genetic treatment. However, all ADA-deficient patients were still receiving PEG-ADA treatment during the trials, which complicates the assessment of clinical benefits that can be exclusively attributed to gene therapy. The T-cell gene therapy studies, however, demonstrated that gene-modified T cells could have very long-term survival *in vivo*, as they have persisted for more than 14 years in the first treated patient. However, the lifespan of these mature lymphocytes cannot be assumed to be unlimited, and this approach intrinsically requires patients to receive periodic treatment to replace dying gene-corrected lymphocytes. The successful genetic correction of the patients' HSCs would theoretically avoid the need for repeated treatments and has been pursued by a series of independent clinical trials.⁷

In 1992, a gene therapy trial targeting bone marrow progenitors and peripheral lymphocytes in two ADA-deficient patients resulted in the improvement of their immune function, with normalization of lymphocytes counts and T-cell proliferation responses to antigens and mitogens.⁷ There was also evidence of successful transduction of hematopoietic progenitor cells, demonstrated by the detection of the ADA gene vector in DNA extracted from blood cell colony-forming units (CFUs) in both patients, with frequencies ranging from 0.8% to 8.5%. Molecular analysis suggested that gene transfer into peripheral lymphocytes led to the persistence of gene-corrected cells in the patients'

circulation for the first 6–12 months after the infusion, and thereafter they were replaced by lymphocytes deriving from the transduced hematopoietic progenitors.⁷

A second stem cell gene therapy trial targeted umbilical cord blood-derived CD34⁺ cells in three ADA-deficient neonates.⁷ This protocol resulted in the presence of a higher percentage of gene transduction among peripheral CD3⁺ T cells (1–10%) than among monocytes and B lymphocytes (0.01–0.1%), thereby indicating that genetic correction provided selective survival advantage to T cells. However, the levels of genetic correction were not sufficient to provide clinical benefit, which was evident when the temporary suspension of PEG-ADA in one patient was unsuccessful, resulting in a marked reduction of lymphocyte numbers and function, followed by an opportunistic infection. Long-term follow-up of these patients has shown the presence of circulating gene-corrected cells for over 5–7 years after treatment.

In 1993, in a multicenter European trial three patients were reported to have received ADA gene transfer into their bone marrow HSCs. Unfortunately, no clinical improvement or long-term presence of the transferred gene could be demonstrated by the investigators.⁷

Altogether, the first series of HSC gene therapy trials for ADA deficiency showed that the efficiency of gene transfer and gene expression was low, and substantiated the need for improvement of gene transfer vectors and transduction procedures. Several research groups in Europe, the USA and Japan have since then proposed various modifications to the gene therapy protocols to increase its efficiency. (Fig. 86.3)

In 2002, Aiuti et al.⁸ reported on a gene therapy study in two ADA-deficient SCID patients, which included the administration of nonmyeloablative conditioning (4 mg/kg busulfan) prior to the infusion of gene-corrected autologous bone marrow CD34⁺ cells, and the absence of PEG-ADA treatment. The authors showed that this protocol resulted in significant immunologic and metabolic improvement. Transient myelosuppression developed, with neutrophil counts returning to minimal normal levels at 21 days. Increases in T, B and NK cells were observed, with an increase in CD4⁺CD45RA⁺ naïve T cells and T-cell receptor excision circles (TREC), also suggesting normal thymic function. T-cell proliferation to mitogens and antigens and T-cell receptor repertoire were restored. Serum IgG, IgA and IgM increased to normal levels, which correlated with positive responses to routine immunizations. No adverse effects were observed, and the two patients (and six additional unpublished patients) were apparently well without receiving PEG-ADA treatment or immunoglobulin replacement. The study demonstrated that this form of gene therapy could cure ADA deficiency and yield better results than those obtained in two previous trials performed in the absence of myeloablative chemotherapy.

In 2001, four ADA-deficient patients received gene therapy in the U.S., while continuing PEG-ADA treatment.⁹ Retroviral gene transfer into bone marrow CD34⁺ cells from these patients has resulted in low levels (0.01–0.1%) of retroviral marking and no clinical benefit, suggesting that the presence of PEG-ADA might have interfered with the selective advantage of gene-corrected cells.

Based on this hypothesis, two patients were treated in a Japanese trial after withdrawal of PEG-ADA treatment and in the absence of myeloablation.¹⁰ These patients showed a slow but definite increase in peripheral blood lymphocyte numbers. At the last reported follow-up, 2 years after treatment, the patients were apparently well in the absence of PEG-ADA.

An additional recent trial in London of retroviral ADA gene transfer into bone marrow CD34⁺ cells by Gaspar and colleagues showed

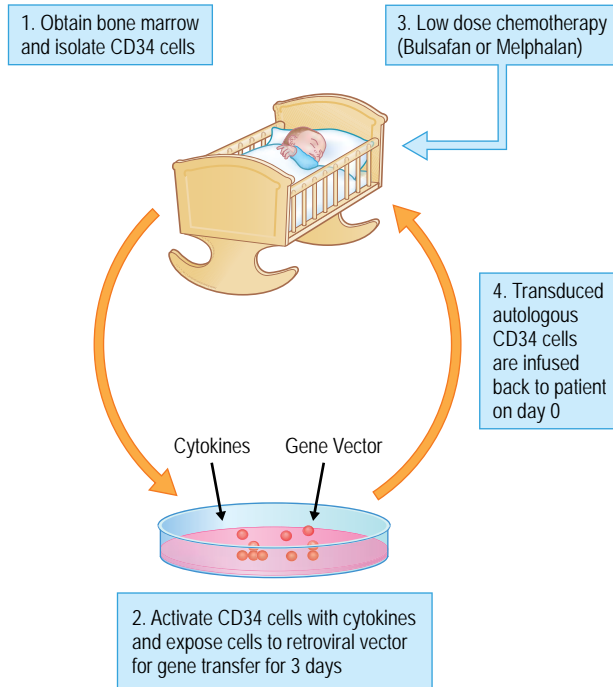

Fig. 86.3 ADA deficiency gene therapy.

successful immune reconstitution after myeloablation and in the absence of PEG-ADA.¹¹ The future form of gene therapy for ADA deficiency is likely to depend upon the use of cytoablation, which appears to favor prompt immune reconstitution.

GENE THERAPY FOR CHRONIC GRANULOMATOUS DISEASE

Patients with chronic granulomatous disease (CGD) have increased susceptibility to pyogenic and fungal infections as a result of poor or absent neutrophil oxidase activity (Chapter 21). A defect in any of four proteins of the NADPH oxidase complex can be responsible for this disease, with about two-thirds of the patients with CGD having a deficiency in the X-linked gene encoding one of these proteins, *gp91phox*. CGD can be cured with an HLA-identical allogeneic bone marrow transplant (BMT); however, haploidentical T cell-depleted BMT is not similarly successful owing to toxicity from myeloablation regimens or to GvHD, resulting in high mortality. Gene therapy experiments have been performed in mice with targeted disruptions of either *p47phox*, the most common gene causing the autosomal recessive form of CGD, or *gp91phox*, demonstrating correction of oxidase activity, protection from bacterial infections, and reduction of excessive inflammatory disease.¹² In addition, studies of CGD female carriers have shown that clinical benefit in humans may require as little as 5% of neutrophils with normal oxidase activity.¹²

After the demonstration of successful *in vitro* correction of human cells, phase I clinical trials were carried out for CGD due to *p47phox* deficiency and for CGD caused by mutations in *gp91phox*. Mobilized

KEY CONCEPTS

GENE THERAPY FOR CGD

- >> Oxidase activity correction of 5% of neutrophils may be sufficient to provide protection against infections and granuloma formation.
- >> Sustained clinical and laboratory improvement was reported in two CGD patients who received gene-corrected autologous HSCs, after non myeloablative chemotherapy.
- >> Adverse effects, including transient myelosuppression, were secondary to chemotherapy.
- >> Corrected cells had retroviral insertions in three genes, *MDS1-EVI1*, *PRDM16* and *SETBP1*, which caused their activation and non-malignant clonal cell expansion.

peripheral CD34⁺ cells from CGD patients were collected and transduced with retroviral vectors. Oxidase-positive neutrophils, used as a measure of transduction efficiency, were observed at low frequencies (0.004–0.2%) up to 6 months after infusion. Overall, the modest results of the initial gene therapy trials for CGD were probably the consequence of reduced transduction of early hematopoietic progenitors.¹³ Ott and colleagues¹⁴ recently reported significant progress, with clinical improvement in two adults with X-linked CGD following a gene therapy protocol that used a nonmyeloablative chemotherapy regimen consisting of busulfan at 8 mg/kg. CD34⁺ cells were isolated from peripheral blood after mobilization with G-CSF and transduced with a retroviral vector carrying the *gp91phox* gene. Transient myelosuppression occurred after chemotherapy, and blood cell counts recovered gradually to normal levels around day 30. Gene-modified cells increased from 10–20% of peripheral blood leukocytes soon after infusion to 40–60% after 7 months. The levels of gene-marked T cells were 2–7% in one patient and 0.4–5% in the other. For B cells, the marking was 17% and 11%, respectively. Significantly, both patients had resolution of chronic infections (pneumonia due to *Aspergillus fumigatus* and pulmonary abscesses due to *Staphylococcus aureus*, respectively) within 2 months of gene therapy. Analysis of DNA from leukocytes of these patients showed a nonrandom distribution of retroviral insertions, with clustering in the *MDS1-EVI1*, *PRDM16* and *SETBP1* loci. Clones carrying these integration sites were found to have undergone *in vivo* expansion starting from 3 months after therapy, and stabilization after 10 months. This particular cell expansion probably contributed to the therapeutic efficacy of the procedure. However, whether or not these clones are at increased risk for future malignant transformation remains unclear. One of these two patients died 24 months after the gene therapy from a bacterial infection with colon perforation and sepsis, and it was reported that there had been a decrease in the NADPH oxidase activity of his granulocytes. Investigations are still preliminary.¹³

Compared to the earlier trials, the results of this study suggest that gene therapy protocols for CGD, and other PIs in which there is no physiologic survival advantage for corrected cells, may benefit from myeloablation. In addition, more efficient gene transduction, to generate a large proportion of corrected cells, will improve the clinical benefits. Towards this goal, recent work has focused on the generation of gene transfer vectors based in lentiviruses pseudotyped with the RD114

envelope (derived from a feline retrovirus) and has shown high levels of oxidase correction and increased human cell engraftment in the NOD/SCID mouse model.²

■ GENE THERAPY FOR LEUKOCYTE ADHESION DEFICIENCY TYPE I ■

Leukocyte adhesion deficiency (LAD) type I is an autosomal recessive disease caused by deficient expression of CD18, a cell membrane adhesion protein that is essential for migration of neutrophils from blood vessels to sites of inflammation (Chapters 12 and 21). LAD patients have recurrent and severe bacterial infections that shorten their life expectancy. The only curative treatment for LAD has been BMT. A human clinical gene therapy trial was conducted for LAD type 1, using G-CSF-mobilized peripheral CD34⁺ HSC transduced with a retroviral vector carrying the CD18 cDNA.¹⁶ One month after infusion of transduced cells, two patients demonstrated that 0.03–0.04% of circulating myeloid cells contained the retrovirally transduced gene. However, these cells had no intrinsic survival advantage and were not detectable at the 2-month post-treatment evaluation. Considering that, as with CGD, LAD neutrophils may not have a survival advantage in their development, future clinical trials may consider including myeloablation to increase the chances of engraftment and differentiation of gene-corrected cells. Experimental results in a canine model using nonmyeloablative conditioning prior to gene therapy support this concept. In 6 of 11 treated dogs with a severe LAD deficiency, up to 8.4% of CD18 leukocytes retained the gene construct one-year later, with reversal or moderation of the phenotype, and marked improvement of neutrophil migration to extravascular spaces.¹⁵

■ GENE THERAPY FOR X-LINKED SCID ■

X-linked SCID (XSCID) is the most common genetic form of SCID and is caused by deleterious mutations in the *IL2RG* gene that encodes for the IL-2 receptor common γ (γ c) chain, a transmembrane protein in the cytokine receptor gene superfamily (Chapter 35). Patients with XSCID do not produce T and NK cells, and their B cells are functionally impaired. *In vitro* experiments with human XSCID cells and *in vivo* mouse models have shown that correction of γ c expression and function, as well as the restoration of XSCID immune defects, was possible by using retroviral vector gene transfer.

Two gene therapy trials for XSCID have been conducted in Europe, one at the Necker Hospital in Paris, and the second at Great Ormond Street Hospital in London.^{18, 19} These studies have shown that infants with XSCID who received an infusion of autologous bone marrow cells corrected by *IL2RG* gene transfer can experience significant immune reconstitution. In both protocols CD34⁺ cells were isolated from bone marrow, activated with cytokines, and exposed to a supernatant containing retroviral vectors carrying *IL2RG* cDNA at high titers. Transduced cells were infused back to patients at a dose of 1.1–22 million cells/kg. Eleven of 14 infants for whom published data are available (10 treated in France and four in England) developed normal T-cell counts, and showed normal proliferative responses to mitogens and antigens.^{19, 20} Gene-corrected NK cells were detected, and about 1% of B cells contained the corrected gene. Antibody responses to vaccines were tested and found to be

adequate, which allowed most treated patients to discontinue immunoglobulin supplementation, thus suggesting some advantage of the procedure over haploidentical HLA BMT. One patient who did not experience immune reconstitution had previous disseminated BCG infection and an enlarged spleen that might have trapped the gene-corrected cells. The one patient who received less than 3 million transduced CD34⁺ cells/kg did not develop a satisfactory number of T cells and later underwent successful haploidentical BMT. Expression and function of γ c have persisted to date in all other patients, as long as 6 years after the therapy, suggesting that long-term correction has been obtained.²⁰

The same gene therapy protocol was also used to treat two older XSCID patients, aged 20 and 16 years. This attempt was reported to have failed, and it was suggested that older age may limit the efficacy of XSCID gene therapy.²¹ One of the patients was followed up to 2 years after treatment: he did not show immunological improvement, and the presence of gene-corrected cell lineages was estimated to be less than 1% by quantitative PCR. The second patient died from severe pre-existing and recurrent skin and lung infections 1.5 years after treatment. He had evidence of gene-corrected peripheral blood T cells only up to 4 months of follow-up. The transient presence of cells containing the retroviral vector in this patient is consistent with engraftment of transduced committed progenitors with a limited lifespan. Among the reasons for the lack of success in these two patients is that the dose of transduced CD34⁺ cells may have been inadequate to achieve significant number of corrected T cells and immune reconstitution. One patient received a low dose of 0.7×10^6 transduced CD34⁺ cell/kg. The other received 4.5×10^6 CD34⁺ cell/kg; however, transduction efficiency was only 13%.

At the National Institutes of Health, a gene therapy clinical trial is being conducted as a salvage treatment for patients who have received BMT and have failed to develop lasting T-cell function.²² Three patients (10, 13 and 14 years of age, respectively) have been treated using *ex vivo* transduction of CD34⁺ cells obtained from peripheral blood by apheresis, after mobilization with granulocyte colony-stimulating factor (G-CSF). Although the presence of peripheral T cells carrying the correct copy of the *IL2RG* gene has been demonstrated in all three patients, only one has shown a high retroviral vector copy number in his T cells (average of 1.11–1.35 vector copies/cell), and progressive replacement of the residual T cells from his previous bone marrow donor with autologous T cells. Up to 18 months post gene therapy, T-cell proliferative responses to mitogen and *Candida* antigen are

KEY CONCEPTS

GENE THERAPY FOR XSCID

- Infants with XSCID were the first individuals to be effectively treated by gene therapy, achieving sustained immunological restoration.
- Cellular and humoral immune functions of the infants with XSCID are restored by autologous gene-modified bone marrow CD34⁺ cells.
- Development of T-cell lymphoproliferative disease is a risk factor for gene therapy of XSCID.
- Gene therapy for XSCID is an alternative treatment for patients who do not have an HLA-matched sibling donor for bone marrow transplantation and over 3.5 months of age.

normal in this patient, although antibody response remains poor. The other two patients have not developed significant immunological changes. However, the clinical status of both patients has improved.

The excitement from the gene therapy success in XSCID infants was partially set back by the occurrence of T-cell leukemia-like disease in three patients in the French study, which will be discussed in the next section. Because of this complication, the gene therapy trial in France was stopped voluntarily by the investigators, and in England new enrollees have been considered on a case-by-case basis. In the USA, XSCID gene therapy trials are allowed to recruit patients who have failed a previous HSCT, or who carry clinical complications (e.g., viral infections) that increase the mortality risk of BMT.

LEUKEMIA IN THE XSCID TRIAL GENE THERAPY PROTOCOL

The two youngest infants (respectively 1 and 3 months of age at treatment) in the French XSCID gene therapy trial developed T-cell leukemia respectively 30 and 34 months after the infusion of corrected cells.²³ A third patient, who received gene therapy treatment at 8 months of age, developed T-cell lymphoma 35 months after treatment.²⁴ For the treatment of their neoplastic diseases all patients received anti-leukemic chemotherapy, and one received an allogeneic BMT when his response to chemotherapy did not eliminate the leukemic clone. This patient later experienced recurrence of his leukemia and died. The other two patients are currently in remission and apparently well, with no antibiotic prophylaxis or immunoglobulin supplementation. The fourth case of leukemia in this trial was recently reported to have occurred 68 months after gene transfer.

The first two patients presented with lymphocytosis, anemia, low platelet counts and splenomegaly. Flow cytometry studies showed that the first patient had a single T-cell clone with a $\gamma\delta$ T-cell receptor; the second had three different T-cell clones with $\alpha\beta$ T-cell receptors. Inappropriate expression of the LIM-domain-only-2 (*LMO-2*) transcription factor, due to insertion of the retroviral vector close to the 5' end of the *LMO2* gene locus, was found in both cases (Fig. 86.4). *LMO2* is expressed in early hematopoietic progenitors, and around 10% of T-cell leukemias have chromosomal translocations involving this locus. The third patient had a presentation more like that of lymphoma than leukemia, with enlarged mediastinum and lymph nodes, and with good response to corticosteroids. His T-cell clone was a double-negative CD3⁺CD4⁺CD8⁺ T cell with at least three different retroviral insertions, including *LMO2*, although the role of this gene in the development of this neoplasia is less clear than in the previous two cases. Before the first case of leukemia in gene therapy patients occurred in 2002, retroviral insertional mutagenesis in hematopoietic cells was assumed to be an event that occurred at random and with a very low probability of adverse consequences. In 2003, a committee of experts appointed by the American Society of Gene Therapy reviewed all published and unpublished studies of HSC transduced with replication-incompetent retroviral vectors.²⁵ Both animal models and more than 40 clinical trials did not show adverse effects attributable to the integration of the gene vector, with the exception of one study describing myeloid leukemia in a mouse that received mouse bone marrow transduced with a truncated nerve growth factor receptor gene.²⁶ Clinical trials have used retroviral vectors to transfer marker genes, anti-HIV genes, genes conferring resistance to cancer chemotherapy, and genes to correct inherited disorders,

with follow-up for more than 10 years in some cases, with no evidence of mutagenesis induced by retroviral gene transfer. However, most of these studies achieved only very low levels of retroviral transduction.

In addition to increased transduction efficiency, compared to previous clinical trials of retroviral gene therapy into HSCs, genetic and environmental

Fig. 86.4 Retroviral insertion sites in the *LMO2* gene identified in leukemic cells from two patients who received gene therapy for X-linked severe combined immunodeficiency and presented with T-cell proliferative diseases at 30 and 34 months follow-up, respectively. Abnormal constitutive expression is driven by the enhancer element present in the retroviral vector.

CLINICAL RELEVANCE

LEUKEMOGENESIS IN GENE THERAPY

- >> Four of 11 XSCID patients in a gene therapy trial conducted in France developed T-cell leukemia between 30 and 68 months after gene therapy. After anti-leukemic treatment, two of the patients are in remission, but one child had a relapse and died.
- >> The first two patients were the youngest to be treated with gene therapy (1 and 3 months of age, respectively).
- >> T-cell clones from these patients had abnormal expression of the *LMO2* gene, a known oncogene, driven by gene vector insertions. These clones also contained chromosomal abnormalities, such as translocation and trisomy 10.
- >> The third patient was 8 months old at the time of treatment, and had T-cell clones with at least three retroviral insertion sites, including *LMO2*.
- >> Studies on retroviral integration sites suggest that these occur preferentially near the 5' end of gene transcription units.
- >> The estimated risk and the risk factors for leukemogenesis in gene therapy are unknown. Other XSCID patients treated with gene therapy and followed for a similar period have not presented with similar adverse events.

influences might have contributed to the development of leukemia in the three XSCID patients. The first of these had experienced a varicella infection just before the amplified clone was detected, and had a family history of childhood cancer. Leukemic cells from both patients had cytogenetic abnormalities often found in malignant cells: a chromosome 6;13 translocation in the first patient; trisomy 10 plus a SIL-TAL1 fusion transcript in the second case. An additional potential risk factor in both children was their young age at treatment. Both had been diagnosed with XSCID at birth based on family history, and were treated at 1 and 3 months of age, respectively. The small size of the infants not only resulted in their receiving large doses of gene-corrected cells (18 and 20 million CD34⁺ cells/kg body weight), but their cells were noted to proliferate more vigorously in the transduction culture than those of the older subjects. HSC obtained from very young patients may, like those from cord blood, have an intrinsically high capacity for replication, possibly increasing their risk of having a harmful gene insertion during retroviral transduction.

The fact that the *LMO2* locus was a target for insertional mutagenesis in both XSCID leukemia cases suggests that inappropriate *LMO2* activation in developing T cells combined with the restored γ c chain can lead to excess cell proliferation, accumulation of oncogenic changes, and ultimately leukemia. Dave et al.²⁷ have provided interesting data that support this hypothesis. In their database of 3000 hematopoietic tumors induced in mice by replication-competent retroviral viruses, they found one case of mouse leukemia with integrations in both *LMO2* and *IL2RG*. The probability for these two integrations to occur by chance in the same tumor is extremely low and suggests synergism between these two genes. However, the molecular mechanisms of how the co-expression of *LMO2* and γ c lead to leukemia in pre- or post-thymic cells and many other aspects of the oncogenesis in these patients are not clear.²⁸ Further clinical and basic research is needed to identify risk factors for the development of neoplasias by insertional mutagenesis. In addition, *in vitro* and *in vivo* models are needed to test safer gene therapy approaches. For example, comprehensive identification of retroviral integration sites has become possible with the availability of the complete human genome sequence.²⁹ Analysis of the identified integration sites of retrovirus and lentivirus-based vectors in HeLa cells, human peripheral blood cells and CD34⁺ cells have revealed a tendency of these vectors to integrate in actively transcribed genes.

■ GENE THERAPY FOR JAK3-SCID ■

JAK3 is a lymphoid tissue-specific tyrosine kinase that binds to γ c and is therefore involved in the signal transduction of IL-2, IL-4, IL-7, IL-9, IL-15, and IL-21. Mutations of *JAK3* can result in an autosomal recessive form of SCID, with clinical characteristics virtually identical to those of XSCID, except for the fact that JAK3 deficiency can also be found in female patients (Chapter 35). Retrovirally mediated gene correction has been effective for reconstitution of IL-2 and IL-4 responses in JAK3-deficient cell lines, and preclinical *in vivo* studies have demonstrated the efficacy of retrovirally mediated gene correction of JAK3 deficiency in JAK3 knockout mice.³⁰

Based on these results, a clinical trial was designed at the St Jude Children's Research Hospital in Memphis to attempt genetic correction of bone marrow CD34⁺ cells of a JAK3-deficient patient who had failed BMT.³¹ An infusion of retrovirally transduced cells was carried out twice in this patient, resulting in low levels of marking without significant

changes in immunological status. The reasons for these unsatisfactory results remain unclear.

■ GENE THERAPY FOR WISKOTT-ALDRICH SYNDROME ■

The Wiskott-Aldrich syndrome (WAS) is an X-linked hematological disorder characterized by eczema, thrombocytopenia, and impaired cellular and humoral immunity. WAS is caused by defects in the WAS protein (WASP), which links the cytoskeleton to intracellular signal transduction pathways (Chapter 35). Severe hemorrhage, disseminated viral or other opportunistic infections, autoimmune disease or lymphoma can cause recurrent and chronic illness and premature death in WAS patients. HSCT from an HLA-identical sibling is the treatment of choice and can be curative, but only a minority of patients have such a donor available. The risks of mortality and adverse effects are much higher when alternative donors are used, such as a haploidentical HLA parent. Gene therapy has therefore been proposed as an alternative, supported by the observation that spontaneous somatic mutations restoring WASP function are associated with a survival advantage of gene-corrected cells over *WASP*-deficient populations; clinical trials of gene therapy for WAS are under development in Europe.

Preclinical studies in *WASP* knockout mice and in human cell lines have shown that retroviral transduction corrects (although mostly only partially) the biological and immunological defects seen in these models (e.g., increased actin polymerization and functional correction of T cells following transduction). Strom et al.³² reported increased specific T-cell responses to influenza as a result of the transplantation of retrovirally transduced HSC in lethally irradiated mice. They also demonstrated restoration of proliferative and IL-2 responses to TCR stimulation. Most recently, Dupre et al.³³ and Charrier et al.³⁴ showed efficacy of WAS gene transfer into mice and human HSC using a lentiviral vector containing the WASP gene, driven either by its own promoter or by the PGK promoter.

■ GENE THERAPY FOR OTHER PRIMARY IMMUNODEFICIENCY DISEASES ■

There are a number of other PIs being investigated for potential treatment with gene therapy (Table 86.1). In several cases, the proof of principle has been obtained in patient-derived primary cells or cell lines. We briefly discuss some examples in which preclinical studies have progressed to the stage of *in vivo* experimentation in mouse models.

X-linked hyper-IgM syndrome type-1 (XHIM1) is caused by defects in the gene for CD40 ligand (CD40L) and is characterized by lack of immunoglobulin switching and defects in cellular immunity owing to the impaired interaction between CD40L (expressed by normal CD4 T cells) and CD40 on B cells (Chapter 35). Studies in mice exploring the possibility of gene therapy for this disease demonstrated that tightly controlled regulation of the expression of CD40L is important in order to avoid uncontrolled lymphoproliferation. CD40L knockout mice that received bone marrow progenitors transduced with the *CD40L* cDNA developed normal humoral and cellular immunity. However, 12 of 19

mice developed lymphoproliferative disorders.³⁵ These results emphasize the complexity and danger of gene therapy when it is aimed at correcting highly regulated genes. Efforts to develop human gene therapy for XHIM1 now include effective regulatory elements for CD40L expression.

Deficiency of ZAP-70, another signal transduction protein, results in an absence of mature circulating CD8 T lymphocytes and TCR signal transduction defects in peripheral CD4 T cells (Chapter 35). Preliminary experiments in patient-derived T-cell lines and primary T cells have indicated the feasibility of the gene correction approach for this disease. *In vivo* experiments of retrovirally mediated gene transfer into bone marrow cells of ZAP-70 knockout animals resulted in the development of mature, polyclonal and functional T lymphocytes in treated animals.³⁶ Potential deleterious effects of the 'ectopic' expression of ZAP-70 in cell types other than T cells is a reasonable concern, because of the characteristic restricted expression of the ZAP-70 protein in specific lymphoid lineages. An alternative solution to this problem was recently explored by Adjali et al.,³⁷ who injected a ZAP-70 lentiviral vector into the thymus of ZAP-70 knockout mice. These experiments resulted in differentiation of mature thymocytes and peripheral ZAP-70-expressing T cells that were responsive to alloantigens both *in vitro* and *in vivo*. Altogether, these data indicate that retrovirally mediated gene transfer of the ZAP-70 gene may prove to have a therapeutic benefit for patients with ZAP-70 deficiency.

Defects in Bruton tyrosine kinase (BTK) cause X-linked agammaglobulinemia (XLA), which presents with an absence of B cells, low immunoglobulin levels and frequent bacterial infections (Chapter 34). Currently, XLA patients receive supportive therapy with prophylactic antibiotics and IVIG; these treatments offer considerable protection, which is, however, expensive and incomplete. Mouse models of XLA have successfully been corrected with retroviral vectors carrying the BTK gene, restoring B-cell numbers and T cell-independent response.³⁸ A survival advantage of normal B cells over cells with BTK mutations has been demonstrated. The application of gene therapy to this disease would include risks that need to be balanced with the relatively safe administration of IVIG.

Interleukin-7 receptor α -chain (IL7RA)-deficient SCID, and recombination activating gene 1 (RAG1)/RAG2-deficient SCID are other forms of PI for which murine models of gene therapy have shown functional correction of immune function. In all cases, retroviral transduction of bone marrow cells with therapeutic retroviral vectors was performed, followed by transplantation into the respective knockout mouse model.¹⁸ Successful immune reconstitution of both RAG1 and RAG2 knockout mice was achieved by transducing their HSCs with a retroviral vector carrying the RAG1 cDNA or the RAG2 cDNA, respectively.^{39,40} The RAG1 and RAG2 vectors were detected in lymphoid cells, but not in myeloid cells, suggesting the strong survival advantage conferred by these genes similar to other SCID genes. Of note, in the case of RAG1, one of the treated mice developed lymphoproliferative disease, warning investigators of the need for regulated expression of this gene. Splenomegaly secondary to neutrophil infiltration was observed in the IL7RA knockout mouse model, suggesting that IL-7 activation signals are not limited to lymphocytes and suggesting potential toxic effects for clinical applications.¹⁸ The correction of a mouse model of a radiosensitive form of SCID, due to mutations in the *Artemis* gene, was achieved by transduction of mouse HSC from the *Artemis* knockout mice with lentiviral vectors expressing human *Artemis* and transplant of the gene-modified HSC back to the mice, after they received submyeloablative dose of Busulfan. No side effects were reported.⁴¹

■ GENE THERAPY FOR HUMAN IMMUNODEFICIENCY VIRUS (HIV) INFECTION ■

HIV infection leads to the development of the acquired immunodeficiency syndrome (AIDS), the most common secondary immunodeficiency due to infection in developed countries. Several gene therapy initiatives were developed in the early 1990s, but were unsuccessful owing to the low efficiency of the technology available to transduce HSC. Progression of HIV infection to AIDS is currently being prevented by early detection and the use of a cocktail of antiviral drugs collectively called highly active antiretroviral therapy (HAART). Ten years after the introduction of HAART, experience with these drug regimens is satisfactory but accompanied by significant side effects, poor patient compliance and the development of resistance, secondary to the need for lifelong treatment. No HAART regimen has shown to be able to consistently eradicate viral infection (Chapter 37).

Gene therapy strategies to control HIV infection may have at least an adjuvant role in the current clinical management of the disease. Genetic intervention has been suggested in order either to induce anti-HIV immunity or to introduce anti-HIV protective genes into T cells or into hematopoietic cells. The major HIV genes involved in its replication and pathogenesis have been well characterized, and clever interventions to neutralize these genes have been proposed. These include transdominant negative proteins, intracellular antibodies, antisense sequences, ribozymes and molecular decoys that inhibit or sequester HIV proteins (Table 86.4). In addition, combinations of these mechanisms have also been proposed, such as a triple combination of a ribozyme targeting Tat and Rev, a TAR RNA decoy and an anti-CCR5 ribozyme.⁴² Most anti-HIV gene therapy approaches have in common the use of a retroviral vector and being efficient at inhibiting HIV replication in T cells or hematopoietic CD34⁺ cells *in vitro*. However, only few clinical trials have been reported.⁴³ In one of the earliest it was shown that transduced CD4 T cells expressing RevM10, a genetically engineered dominant negative mutant protein of HIV Rev, had a survival advantage over cells that were not expressing this gene. This study showed that survival advantage that had been shown *in vitro* could also be demonstrated in HIV-infected patients.⁴⁴ Similar results were obtained using ribozyme targeting the HIV promoter and the HIV *tat* RNA message. In addition, more recent studies have focused on the transduction of anti-HIV genes into CD34⁺ hematopoietic stem cells, to take advantage of their self-renewal capacity and to allow thymic T-cell differentiation. However, the low transduction efficiency of CD34⁺ cells has resulted in very low levels of engraftment of gene-modified CD34⁺ cells, although these vector-containing cells persisted for over 3 years in most patients.^{43,44}

Current studies are focused on increasing the effective rate of transduction working with lentivirus-derived vectors, which have the advantage of being more efficient in the transfer of genes to nondividing cells. Perez et al.⁴⁵ demonstrated a significant reduction of cytopathic effects and the production of soluble HIV protein p24 when CD4 T cells transduced with an HIV-based gene vector carrying the membrane-bound gp41 fusion inhibitor were challenged with a T-cell tropic HIV strain. Large animal models continue to be fundamental for the development of anti-HIV therapeutic genes, such as the work of Braun et al.⁴⁶ in monkeys using a HIV-1 based vector carrying an antisense

Table 86.4 Examples of anti-HIV gene therapy strategies

Inhibitory interventions	Strategies in clinical trials
Transdominant negative proteins Ribozymes Sense and antisense sequences	M10Rev (Rev transdominant protein) Rr2 (Tat targeted ribozyme) VRX496 (antisense for Env gene)

molecule targeting the envelope sequence. Rhesus monkey bone marrow CD34⁺ cells were transduced and cultured in thymus stroma to induce T-cell development. These gene-modified T cells were resistant to simian HIV replication. Clinical trials using different anti-HIV genes and lentivirus-derived gene vectors are being developed. No definite results have so far been reported.⁴⁷

CONCLUSIONS AND FUTURE DIRECTIONS

Current treatment for many PIs and for HIV infection is not optimal and justifies the search for alternative treatments. For example, in the case of SCID, in many patients enzyme replacement or BMT often remains inadequate, with increased susceptibility to infections, autoimmunity, and/or GVHD. Gene therapy is a promising alternative treatment for primary immunodeficiencies, provided that restoration of an appropriate level of gene expression can be achieved in multipotent, self-renewing stem cells. PIs are the first group of diseases in which gene therapy has been successful in human trials, with complete restoration of immune competence in infants with XSCID and ADA-deficient SCID. Unfortunately, at the same time, the application of gene therapy in XSCID has also made evident for the first time the risk of insertional mutagenesis. Several hypotheses are being investigated concerning the roles of specific gene expression, gene vector dose and patient age. Because of the overall limited clinical experience, it appears that the risk of oncogenesis in gene therapy trials will be realistically estimated only after treating more patients and following them closely over the long term, with careful assessment of insertion sites and clonality. Future directions to improve the safety of gene therapy in this regard include the development of vectors with reduced ability to activate nearby genes, using strategies such as 3' LTR deletion.

New approaches are being suggested, such as the direct intra-femoral injection of retroviral vectors, as an alternative to avoid deleterious effects of *ex vivo* manipulation. McCauslin et al.⁴⁸ used this technique to correct JAK3 knockout mice with a JAK3 cDNA vector. Five of 12 injected mice had increased naïve T-cell counts. Specific antibody titers and mitogen proliferative responses were also improved in two of five treated mice studied. Although a minority of the treated mice were reconstituted, this study demonstrated the feasibility of direct vector injection. Another proposal is the intravenous injection of retroviral vectors, tested in a canine model of XSCID, and a mouse model of ADA-SCID.⁵⁰ *In vivo* approaches are appealing to surpass loss of HSC engraftment potential during *in vitro* cultures required for gene transduction; however, the safety issues relating to retroviral insertion in these new approaches may need to be completely addressed before *in vivo* gene therapy is used in clinical trials.

Other methods for gene delivery are being developed to achieve gene transfer targeted to specific genome sites, which would ideally avoid integrations in undesirable regions of the genome, including the vicinity of known oncogenes. These methods include the PhiC31 integrase system,⁵¹ and specific site-directed recombination using modified zinc finger molecules.⁵² The PhiC31 uses a rare 34-bp recognition sequence that allows integration in unique specific sites of the genome. Ishikawa et al.⁴⁷ demonstrated the feasibility of this approach using a human T-cell line deficient in the γ c chain and characterized the insertion of the gene vector, which appeared to reproducibly involve intergenic regions in chromosomes 13 and 18, and lead to stable expression with correction of the IL-2 signaling response. In developing the nuclease/zinc finger approach, Urnov and colleagues⁵² demonstrated that gene repair strategies may work by showing modification of an *IL2RG* point mutation in 5% of T cells *in vitro* and the reversion to wild-type sequence in about 10% of K562 cells engineered to carry a point mutation in *IL2RG*. Although these results are encouraging, both approaches require additional vectors to deliver these recombination enzymes into target cells. In addition, more experiments are needed to assess the intrinsic risk of nonspecific recombination events that may be associated with these strategies.

The successes of XSCID, ADA SCID and CGD gene therapy clinical trials, as well as the unexpected adverse events in a small proportion of treated patients, demonstrate that gene therapy for immunodeficiencies is past its infancy, and has the clear potential to become a viable alternative for the treatment of these otherwise fatal disorders.

Glucocorticoids

Frank Buttgereit, Markus J.H. Seibel,
Johannes W.J. Bijlsma

87

Glucocorticoids exceed many other drugs in terms of numbers of patients treated, variety of applications and pharmacological experience in humans.¹ Almost 60 years after their introduction into clinical practice, they still represent the most important and most frequently employed class of anti-inflammatory drug, with a steady rise in therapeutic use in recent years.² About 10 million new prescriptions for oral glucocorticoids are issued each year in the USA.² Community survey data estimate the frequency of oral glucocorticoid use as 0.5% of the general population and 1.75% of women aged over 55 years.^{3, 4} Between 56% and 68% of patients with rheumatoid arthritis are treated more or less continuously with glucocorticoids.¹ Glucocorticoids are relatively inexpensive, but owing to the sheer volume prescribed the total market size is about US\$10 billion per year.²

The major reason for their widespread use is simple: glucocorticoids are the most effective (and cost-effective) anti-inflammatory and immunomodulatory drugs available. At the same time, glucocorticoids are prone to cause frequent and serious side effects, especially when used incorrectly.

MECHANISMS OF ACTION

The basis for the use of different dosages of glucocorticoids in different clinical conditions is essentially empirical, as evidence to support preferences in specific clinical settings is scarce.¹ It is clear, however, that glucocorticoid dosages increase with clinical activity and the severity of the disease under treatment. The rationale for this (mostly successful) clinical approach is that higher dosages increase glucocorticoid receptor saturation in a dose-dependent manner (Table 87.1), which intensifies the therapeutically relevant, *genomic* glucocorticoid actions; and it is assumed that with increasing dosages, additional and qualitatively different, *nonspecific*, *nongenomic* actions of glucocorticoids come into play (Table 87.1).

GENOMIC ACTIONS OF GLUCOCORTICOIDS

The anti-inflammatory and immunomodulatory effects of glucocorticoids (GC) are mediated predominantly by genomic mechanisms (Figs 87.1 and 87.2). Binding to cytosolic glucocorticoid receptors (cGCR) ultimately induces (*transactivation*) or inhibits (*transrepression*) the synthesis of regulator proteins.⁵ Between 10 and 100 genes per cell are directly regulated by glucocorticoids, but many genes are regulated indirectly through interaction with transcription factors and co-activators (see below).⁶ It is estimated that glucocorticoids influence the transcription of approximately 1% of the entire genome. In the past few years, our in-depth knowledge of the genomic actions of GCs has greatly increased. Their lipophilic structure and low molecular mass allow GCs to pass easily through the cell membrane and bind to the inactive cGCR (α -form = cGCR α).

KEY CONCEPTS

CHARACTERISTICS APPLYING TO GENOMIC ACTIONS

- >> Physiologically relevant
- >> Therapeutically effective at all dosages, even very small ones (low dose therapy).
- >> Slow; significant changes in the regulator protein concentrations are not seen within less than 30 minutes because of the time required for cGCR activation/translocation, transcription and translation effects.
- >> The GC-induced synthesis of regulator proteins can be prevented by inhibitors of transcription (e.g. actinomycin D) or translation (e.g. cycloheximide).

Table 87.1 Current knowledge on the relationship between clinical glucocorticoid dosing and cellular glucocorticoid actions (From Buttgereit F, Straub RH, Wehling M, Burmester GR. Glucocorticoids in the treatment of rheumatic diseases. An update on mechanisms of action. *Arthritis Rheum* 2004; 50: 3408–3417, with permission)

Terminology (mg prednisone equivalent per day)	Clinical application	Genomic actions (receptor saturation)	Unspecific nongenomic actions	cGCR-mediated nongenomic actions
Low dose (≤ 7.5)	Maintenance therapy for many rheumatic diseases	+ (< 50%)	–	?
Medium dose (>7.5 – ≤ 30)	Initially given in primary chronic rheumatic diseases	++ (> 50 - < 100%)	(+)	(+)
High dose (>30 – ≤ 100)	Initially given in subacute rheumatic diseases	++(+) (almost 100%)	+	+
Very high dose (> 100 mg)	Initially given in acute and/or potentially life- threatening exacerbations of rheumatic diseases	+++ ((almost) 100%)	++	+(+?)
Pulse therapy (≥ 250 mg for 1 or a few days)	Particularly severe and/or potentially life-threatening forms of rheumatic diseases	+++ (100%)	+++	+(+?)

Fig. 87.1 Mechanisms of the cellular action of glucocorticoids. As lipophilic substances, glucocorticoids pass very easily through the cell membrane into the cell, where they bind to ubiquitously expressed cytosolic glucocorticoid receptors (cGCR). This is followed by either the classic cGCR-mediated genomic effects (I) or by cGCR-mediated nongenomic effects (II). Moreover, the glucocorticoid is very likely to interact with cell membranes, either specifically via membrane-bound glucocorticoid receptors (mGCR) (III) or via nonspecific interactions with cell membranes (IV). (From Buttgereit F, Straub RH, Wehling M, Burmester GR, 2004. Glucocorticoids in the treatment of rheumatic diseases. An update on mechanisms of action. *Arthritis and Rheumatism* 50: 3408–3417.)

Fig. 87.2 (A–D) Genomic mechanisms of glucocorticoids. This figure illustrates the different mechanisms by which the activated glucocorticoid receptor complex leads to the induction or to the inhibition of transcription and finally translation/synthesis of specific regulator proteins. Details are given in the text. (From Buttgerit F, Straub RH, Wehling M, Burmester GR, 2004. Glucocorticoids in the treatment of rheumatic diseases. An update on mechanisms of action. *Arthritis and Rheumatism* 50: 3408–3417.)

Structure of the cGCR

The unactivated cGCR is a 94 kDa protein held in the cytoplasm as a multi-protein complex consisting of several heat shock proteins (hsp), including hsp90, hsp70, hsp56 and hsp40 (chaperones) (Fig. 87.3). The cGCR interacts with immunophilins, p23 and several kinases of the mitogen-activated protein kinase (MAPK) signaling system, including Src, which also act as molecular (co)chaperones (Figs 87.1 and 87.3).^{1,7,8} The general function of molecular (co)chaperones is to bind and stabilize proteins at intermediate stages of folding, assembly, translocation and degradation. With regard to cGCR, they also regulate cellular signaling, which includes (i) stabilizing a specific conformational state of cGCR that binds ligand with high affinity; (ii) simultaneously opening the glucocorticoid binding cleft to access by glucocorticoids; and (iii) stabilizing the binding of GR to the promoter.¹

The first step in assembling the multi-protein cytosolic complex is ATP- and hsp40(YDJ-1)-dependent formation of a cGCR-hsp70 complex that primes the receptor for subsequent ATP-dependent activation by hsp90, Hop, and p23.⁹ The glucocorticoid receptor consists of different domains with distinct functions: an N terminal, a DNA-binding domain (DBD) and a ligand-binding domain (LBD) (Fig. 87.3). The N terminal harbors transactivation functions, especially within the 'τ1' region. A motif common to DNA-interacting proteins, the zinc finger

Fig. 87.3 Structure of the cytosolic glucocorticoid receptor. The unactivated (unligated) cGCR is a 94 kDa protein retained in the cytoplasm as a multi-protein complex consisting of several heat shock proteins (hsp), including hsp90, hsp70, hsp56 and hsp40 (chaperones). Furthermore, the cGCR interacts with immunophilins, p23 and several kinases of the mitogen-activated protein kinase (MAPK) signaling system, including Src, which also act as molecular (co)chaperones. An important function of molecular (co)chaperones is to stabilize a specific conformational state of the GC which binds ligand with high affinity (see text). The receptor protein itself consists of different domains: an N terminal, a DNA-binding domain (DBD) and a ligand-binding domain (LBD). The N terminal harbors transactivation functions, especially within the so-called τ1 region. Another major transactivation region is τ2, which can interact with the above-mentioned cofactors. (From Buttgerit F, Straub RH, Wehling M, Burmester GR, 2004. Glucocorticoids in the treatment of rheumatic diseases. An update on mechanisms of action. *Arthritis and Rheumatism* 50: 3408–3417.)

motif, is found twice within the DBD. The LBD consists of 12 α helices, several of which help form a hydrophobic ligand-binding pocket.⁸ The cGCR contains another major transactivation region ('τ2') that can interact with the above-mentioned cofactors (Fig. 87.3). Following glucocorticoid/receptor binding, hsp90 molecules and other chaperones are rapidly shed. This allows translocation into the cell nucleus, where the GC/cGCR complex binds as a homodimer to consensus palindromic DNA sites (GC-responsive elements – GREs).⁵

Translocation into the nucleus

Nuclear translocation of the GC/cGCR complex occurs within 20 minutes. Hormone-directed recruitment of FKBP52 and dynein to the GCR may cause its transport to the nucleus.¹⁰ Depending on the target gene, transcription is then either activated (*transactivation* via positive GRE) or inhibited (*transrepression* via negative GRE) (Fig. 87.2A and B).

Interactions with transcription factors

Besides the interactions of GC/cGCR complexes with GREs, a further important genomic mechanism of GC action is interaction of activated cGCR monomers with transcription factors. Accordingly, although the GC/cGCR complex does not inhibit their synthesis, it modulates the activity of AP-1 (activator protein-1), NF-κB (nuclear factor-κB) and

NF-AT (nuclear factor for activated T cells).^{11–15} This leads to inhibition of nuclear translocation and/or function of these transcription factors, and hence to inhibition of the expression of many immunoregulatory and inflammatory cytokines. Possible mechanisms include:⁵

- Synthesis of I κ B (a specific inhibitor of NF- κ B) induced through GC/cGCR complex–GRE interaction (Fig. 87.2A).
- Protein–protein interaction of the GC/cGCR complex with transcription factors through binding to their subunits (Fig. 87.2C), which prevents their DNA binding.
- Competition for nuclear co-activators between the GC/cGCR complex and transcription factors (Fig. 87.2D).

Inhibition of transcription factor function and the resultant inhibition of protein expression are referred to as *transrepression*. Numerous genes are regulated by this mechanism. It appears that many adverse effects of GC are caused by *transactivation* (i.e., induced synthesis of regulator proteins), whereas many anti-inflammatory effects are mediated by *transrepression* (i.e., inhibited synthesis of regulator proteins). This differential molecular regulation underlies current drug-discovery programs aimed at developing dissociated cGCR-ligands.²

The cGCR β isoform

An alternative splice variant of the cGCR α exists: the cGCR β isoform, which does not bind ligand and has been proposed to inhibit classic cGCR α -mediated transactivation. Recent structural research has shown a possible physical explanation for the lack of hormone binding and the dominant negative actions of cGCR β .¹⁶

Post-transcriptional and post-translational mechanisms

Glucocorticoids also act through post-transcriptional and post-translational mechanisms, e.g., reduction of cytokine mRNA half-life and downregulation of GCR (via reduced mRNA levels and reduced stability of the GCR protein).¹⁷

Glucocorticoid receptor resistance

GCR resistance is an interesting field of research. Several different mechanisms may mediate this phenomenon, among them alterations in number, binding affinity or phosphorylation status of the GCR. Other mechanisms being investigated are polymorphic changes and/or over-expression of (co-)chaperones, increased expression of inflammatory transcription factors, over-expression of the GCR β isoform, the multi-drug resistance pump, and altered mGCR expression.

NONGENOMIC ACTIONS OF GLUCOCORTICOIDS

Some regulatory effects of glucocorticoids arise within seconds or minutes. These are too rapid to be explained as genomic actions, and are attributed to *nongenomic* mechanisms of action. Three different rapid nongenomic actions of glucocorticoids have recently been described.^{1, 18–21}

cGCR-mediated nongenomic actions

Croxtall et al.¹⁹ reported that dexamethasone can rapidly inhibit epidermal growth factor-stimulated cPLA₂ (cytosolic PLA₂) activation with subsequent arachidonic acid release. This effect is thought to be mediated by occupation of cGCR, but not by changes in gene transcription, as the observed effect is RU486 sensitive (i.e., glucocorticoid receptor dependent), but actinomycin insensitive (i.e., transcription independent). It is suggested that chaperones or co-chaperones of the multi-protein complex may act as signaling components to mediate this effect. Following glucocorticoid binding, the cGCR is released from this complex to mediate classic genomic actions. However, there is also a rapid release of Src and other (co-)chaperones of the multi-protein complex, which may cause rapid inhibition of arachidonic acid release. Similarly, cardiovascular protective effects of dexamethasone have been reported which are not genomic (because they occurred too quickly and were actinomycin insensitive) or nonspecific nongenomic effects (because they occurred at a very low dosage (100 nM).²¹ These may involve binding of glucocorticoids to the cGCR, leading to nontranscriptional activation of phosphatidylinositol 3-kinase, protein kinase Akt and endothelial nitric oxide synthase.

Nonspecific nongenomic actions

Under certain circumstances glucocorticoids are administered at very high concentrations (e.g., intra-articular injection or IV pulse therapy). Systemically administered daily dosages >100 mg prednisone equivalent are regarded as ‘very high dose.’ In contrast, ‘pulse therapy’ is the daily administration of ≥ 250 mg prednisone equivalent for one or a few consecutive days²² (Table 87.1). Saturation of all cGCR is almost complete with a daily dose of 100 mg prednisone equivalent, so that specificity, i.e., the exclusivity of receptor-mediated effects, is lost at these high – but clinically relevant – glucocorticoid concentrations.¹⁸ Nonspecific nongenomic actions occur in the form of physicochemical interactions with biological membranes, which probably contribute to the therapeutic effect.¹ A nonspecific intercalation of glucocorticoid molecules into cell membranes is thought to alter cell function by influencing cation transport and increasing mitochondrial proton leak. The resulting inhibition of calcium and sodium cycling across the plasma membrane of immune cells is thought to contribute to rapid immunosuppression and to reduced inflammation.^{1, 18}

The use of such high glucocorticoid doses is confined to certain clinical specialties and has been criticized by endocrinologists and pharmacologists. Unfortunately, scientific evidence on this issue is lacking, as there are no randomized controlled trials. However, high-dose glucocorticoid therapy is often used with clinical success in acute exacerbations of life-threatening diseases and various clinical conditions resistant to other therapies. For example, pulsed IV methylprednisolone is effective in the treatment of systemic lupus erythematosus (SLE). However, these studies were mainly uncontrolled and retrospective in nature. A recent review concluded that intravenous pulses of methylprednisolone rapidly immunosuppresses patients with organ- and/or life-threatening manifestations of SLE. However, the gold standard – 1 g/day for 3 consecutive days – is associated with significant infectious complications, and lower doses may be just as useful.²³

Another example is immune thrombocytopenia associated with SLE where high-dose glucocorticoids are normally (and mostly successfully) used, although comparative studies are lacking.²⁴ It has been calculated that in situations like these, concentrations are achieved *in vivo* that are high enough (around 10^{–5} mol/L) to cause immediate nonspecific

nongenomic effects on immune cells.¹ Intra-articular injections also bring high concentrations of glucocorticoids into contact with inflammatory cells, although it is difficult to assess locally achieved concentrations because crystal suspensions are most often used.

Specific nongenomic actions

Glucocorticoids can also induce specific nongenomic actions mediated through membrane-bound glucocorticoid receptors (mGCR). The existence and function of membrane-bound receptors have recently been demonstrated for various steroids (including mineralocorticoids, gonadal hormones, vitamin D and thyroid hormones).^{1,18,25} Using immunofluorescence, small numbers of mGCR can be demonstrated on human peripheral blood mononuclear cells (monocytes and B lymphocytes) from healthy controls.²⁵ The monoclonal antibody used to detect mGCR also recognized cGCR, suggesting that mGCR are probably variants of cGCR produced by differential splicing or promoter switching. It has also been found that immunostimulation with lipopolysaccharide increases the percentage of mGCR⁺ monocytes; this can be prevented by inhibiting the secretory pathway with brefeldin A. This suggests that mGCR are actively upregulated and transported through the cell following immunostimulation. These *in vitro* findings are consistent with observations that the frequency of mGCR⁺ monocytes is increased in patients with rheumatic disorders, and is positively correlated with disease activity in rheumatoid arthritis.²⁵ The function(s) of mGCR remain unclear, but this observation means that mGCR may be implicated in pathogenesis. Alternatively, and perhaps more likely, they may cause negative feedback regulation.

■ GLUCOCORTICOID EFFECTS ON IMMUNE CELLS ■

Through the above mechanisms, glucocorticoids mediate a fascinating range of anti-inflammatory and immunomodulatory effects when used therapeutically, with virtually all primary and secondary immune cells affected to some extent (Table 87.2).²⁶

■ THERAPEUTIC USE ■

A wide range of GC molecules are available for clinical use: these share a common basic structure and have been modified to improve their usefulness in various clinical applications (Fig 87.4). Despite their widespread use, the designation of GC treatment regimens is often imprecise. Recommendations for a standardized nomenclature for GC therapy are summarized below.²²

TERMINOLOGY

What term should be used to describe this class of drugs?

The term 'steroids' (although very often used) is too broad, as it simply describes chemical compounds characterized by a common multiple-ring structure (including, for example, cholesterol, vitamin D and sex hormones); also, the terms 'corticosteroids' or 'corticoids' are not

Table 87.2 Important effects of glucocorticoids on primary and secondary immune cells (From Buttgerit F, Saag K, Cutolo M, et al. The molecular basis for the effectiveness, toxicity, and resistance to glucocorticoids: focus on the treatment of rheumatoid arthritis. *Scand J Rheumatol* 2005; 34: 14–21, with permission)

Monocytes/macrophages
↓ number of circulating cells (↓ myelopoiesis, ↓ release)
↓ expression of MHC class II molecules and Fc receptors
↓ synthesis of proinflammatory cytokines (e.g., IL-2, IL-6, TNF-α) and prostaglandins
T cells
↓ number of circulating cells (redistribution effects)
↓ production and action of IL-2 (most important)
Granulocytes
↓ number of eosinophil and basophil granulocytes
↑ number of circulating neutrophils
Endothelial cells
↓ vessel permeability
↓ expression of adhesion molecules
↓ production of IL-1 and prostaglandins
Fibroblasts
↓ proliferation
↓ production of fibronectin and prostaglandins

KEY CONCEPTS

GLUCOCORTICOID EFFECTS ON IMMUNE CELLS

- >> Inhibit leukocyte traffic and access of leukocytes to the site of inflammation.
- >> Interfere with functions of leukocytes, fibroblasts and endothelial cells.
- >> Suppress the production and actions of humoral factors involved in the inflammatory process.

sufficiently precise, as the adrenal cortex, from which these designations are derived, synthesizes not only glucocorticoids, but also mineralocorticoids and androgens. For these reasons, the terms 'glucocorticoid' or 'glucocorticosteroid' are scientifically correct, but 'glucocorticoid' is the more widely used.

How can glucocorticoid therapy schedules be described as precisely as possible?

A description has been suggested that is precise regarding the drug, the dosage, the route of administration, and the timing of administration (timing, frequency, duration, sometimes cumulative dosage where appropriate).

Of note is that different glucocorticoid drugs have different potencies. Moreover, glucocorticoids differ in their ability to produce the distinct

Fig. 87.4 Molecular structures of cortisone and commonly used glucocorticoids. Carbon and ring nomenclature is indicated on cortisone molecule.

therapeutic effects discussed above. Drug potencies are usually described by the equivalent dosages (relative potencies) to produce classic genomic effects (Table 87.3). These values have been in use for decades, although experimental and clinical evidence for their precision is weak. Nevertheless, relative potencies are useful in daily clinical practice as a general therapeutic guideline, as long as one avoids using them dogmatically. It has therefore been suggested (i) to continue to use relative potencies until more exact data are available, and (ii) to express doses of different glucocorticoids by converting them into doses of 'prednisone equivalent'; the latter simply means that doses of different glucocorticoids are being expressed in milligrams of prednisone (= mg prednisolone, as the potency of prednisone is equal to that of prednisolone) by using the relative potencies mentioned above.

Recent data, however, indicate that the use of equivalent dosages is valid only if doses less than 100 mg prednisone are considered. At higher dosages nongenomic effects come into play. This is important, as the relative potencies of different glucocorticoids to produce these nongenomic effects are completely different from their classic genomic effects (Table 87.3). For instance, methylprednisolone is often preferred over prednisolone for pulse therapy of exacerbated immunologically mediated disorders in exacerbation. The two drugs have similar genomic potency, but in high-dose therapy the nonspecific nongenomic effect of methylprednisolone is more than three times stronger. This may explain the empirical clinical preference for methylprednisolone. Another example is the very low nongenomic potency of betamethasone, which may be one reason why this drug is rarely used systemically, although it has the same genomic potency as dexamethasone. In summary, the clinical usage of different glucocorticoids is clearly determined by the magnitude of their clinical efficacy, but one underlying reason for that may be their nongenomic potencies.

Table 87.3 Drug potencies of selected glucocorticoids

Cortisol	1 (per definition)
Prednylidene	3.5
Predniso(lo)n	4.0
Methylprednisolone	5.0
Dexamethasone	25
Betamethasone	25

Drug potencies describe the potency of the respective drug to produce classical genomic (anti-inflammatory) effects relative to cortisol. These potencies provide the basis for calculating equivalent dosages (Data from Lipworth BJ, 2000. Therapeutic implications of non-genomic glucocorticoid activity. *Lancet* 356: 87–89).

GLUCOCORTICOID TREATMENT REGIMENS: GENERAL ASPECTS

The current confusion to describe glucocorticoid treatment regimens is exemplified by the different interpretations of the various terms used to describe dosage (very low, low, mild, mild to moderate, moderate, high, very high, ultra-high, and mega) and by the great variation in the interpretation of terms such as 'low-dose therapy,' 'high-dose therapy' and 'pulse therapy.' A clarification of this situation was needed, first for scientific conciseness and to compare clinical trials and, second because glucocorticoid actions are strongly dose dependent both quantitatively and qualitatively. Therefore, the consensus

KEY CONCEPTS

DEFINITION OF CONVENTIONAL TERMS FOR GLUCOCORTICOID DOSAGES

>> Low dose	≤ 7.5 mg prednisone equivalent per day
>> Medium dose	> 7.5 mg, but ≤30 mg prednisone equivalent per day
>> High dose	> 30 mg, but ≤100 mg prednisone equivalent per day
>> Very high dose	> 100 mg prednisone equivalent per day
>> Pulse therapy	≥ 250 mg prednisone equivalent per day for 1 or a few days

statement included also recommendations for the definition of glucocorticoid dosages. The rationale for the terminology suggested is as follows. As mentioned above, glucocorticoids act via genomic and nongenomic pathways. For the genomic effects, the degree of cytosolic receptor saturation is considered a direct modulator of the intensity of (therapeutic) glucocorticoid actions. Unfortunately, there are no precise data describing the relationship between administered glucocorticoid dose and subsequent occupation of the receptors. Moreover, wide inter-individual variations in plasma levels in response to the same oral dose of glucocorticoid have to be taken into account. However, it has been calculated from known binding constants, free glucocorticoid levels and other parameters that oral doses of 7.5 mg and 15 mg of prednisolone result in blood levels 8 hours after the dose that would saturate the receptors to 42% and 63%, respectively. According to these calculations, higher doses (e.g., 100 mg or more) would be required to result in almost complete receptor saturation (Table 87.1). These considerations were the reasons for the suggested terminology, together with the fact that clinicians in their daily practice have already created landmark glucocorticoid doses that are still imprecise in their definition but which clearly group around 7.5, 30 and 100 mg prednisolone equivalent per day.

Low dose

Treatment with doses of up to 7.5 mg prednisone equivalent per day is considered low-dose glucocorticoid therapy because these doses occupy less than 50% of the receptors; are frequently used for maintenance therapy; and may have relatively few adverse effects (such as osteoporosis). The recognition that relative hypocortisolism is present in many chronic inflammatory conditions, such as rheumatoid arthritis and polymyalgia rheumatica, for example, leads some observers to regard low-dose glucocorticoids as replacement therapy for the reduced adrenal production of glucocorticoids.

Medium dose

Glucocorticoid doses >7.5 mg, but <30 mg prednisone equivalent per day are considered medium, because they lead to a significantly higher receptor engagement, ranging from >50% to <100%; are effective if given initially in various conditions of rheumatic diseases (primary chronic rheumatic diseases); are a ‘natural barrier’ in the sense that most rheumatologists/clinical rheumatologists do not initially treat most patients (e.g. those with noncomplicated rheumatoid arthritis or polymyalgia rheumatica) with doses >30 mg; and may have considerable and dose-dependent adverse effects if given for longer periods.

High dose

Treatment with >30 mg and ≤100 mg prednisone equivalent per day is considered high-dose therapy, because these doses significantly increase receptor saturation in a dose-dependent manner, resulting in an almost complete receptor saturation at approximately 100 mg/day, where up to 100% of genomic glucocorticoid effects are assumed to be exerted (Table 87.1); are successfully given as initial treatment for subacute diseases, such as nonlife-threatening exacerbations or visceral complications of rheumatoid arthritis or other connective tissue diseases; and they cannot be administered long term because of the severe side effects.

Very high dose

Dosages >100 mg prednisone equivalent per day are considered ‘very high’, because they lead to virtually 100% receptor saturation with regard to cytosolic receptors. Therefore, a further increase in dose may affect the pharmacodynamics (e.g., receptor offloading and re-occupancy), receptor synthesis and expression, but may also bring additional therapeutic benefit via other mechanisms, namely the above mentioned nongenomic effects. It is not yet clear whether these effects are of direct therapeutic relevance, but experimental data suggest that these differential effects come increasingly into play above ~100 mg/day (Table 87.1). These dosages are frequently and successfully given initially for acute or life-threatening exacerbations of (rheumatic) diseases, such as connective tissue diseases, vasculitis, and rheumatoid arthritis. They cannot be administered long term because of their severe side effects.

Pulse therapy

‘Pulse therapy’ is considered a specific therapeutic entity that refers to the administration of ≥250 mg prednisone equivalent per day (usually IV) for a short period of time (usually 1–5 days or more). It should be stressed that this term refers to the very high dose given, rather than to its intermittent timing of application. The following arguments support this suggestion: first, in clinical practice dosages of 250 mg/day or above are usually only used for pulse therapy. Thus, these dosages are given for a few days only, with a view to quickly reducing them or stopping treatment altogether. Second, the nongenomic potencies of glucocorticoids come into play at such high doses. It is likely that these are the reasons for the clinical observation that very high doses and pulse therapy are generally successful in acute exacerbations of immunologically mediated diseases. The immediate effects produced by very high doses could be additive to the genomic effects mediated by cytosolic GC receptors. The additional quantum of inhibition of the excessive immune processes

could make a crucial contribution to the therapeutic effect by helping to terminate the acute exacerbation. In rheumatology and clinical immunology, acute episodes or particularly severe forms of rheumatic diseases such as systemic lupus erythematosus, vasculitis, polymyositis and rheumatoid arthritis (see below) are examples of the circumstances where very high doses or pulse therapy can be successful. Pulse therapy results in termination of the exacerbation or regression of severe forms of disease in a high proportion of cases, with a relatively low incidence of side effects. Nongenomic mechanisms of GC action may also explain the beneficial therapeutic effect of pulse GC therapy for many other indications. These include the treatment of acute spinal injuries and use in immune thrombocytopenia, juvenile dermatomyositis, juvenile chronic arthritis, optic neuritis, rapid progressive glomerulonephritis, and pemphigus vulgaris. Nongenomic mechanisms offer a possible explanation for benefits, such as very early clinical response, which cannot be extrapolated from the dose–response effects of medium- or low-dose therapy.

Alternate-day regimens

Alternate-day regimens were introduced for long-term oral GC therapy to alleviate undesirable side effects, such as hypothalamopituitary–adrenal (HPA) axis suppression. A single dose is administered every other morning, usually in a dose equivalent to, or somewhat higher than, twice the usual daily dose. The logic behind this is that exposing the body to exogenous GC on alternate days may allow the HPA axis to remain active – however, this only makes sense when the axis is already still active. Unfortunately, patients often experience breakthrough symptoms on the second day of treatment. Alternate-day regimens are used rarely nowadays, except in patients with juvenile idiopathic arthritis, in whom alternate-day glucocorticoid usage results in less inhibition of body growth.

Glucocorticoid withdrawal regimens

Because of the potential side effects, GCs are generally tapered off as soon as the disease is under control. Tapering must be done carefully to avoid recurrence of disease activity and to permit recovery of adrenal function. There have been no controlled, comparative studies for tapering GCs, and the regimen needs to be adjusted according to disease activity, dose/duration of therapy and clinical response. When patients with rheumatoid arthritis are treated with up to 10 mg/day prednisone, the daily dose can be reduced by 2.5 mg every month until 5 mg/day is achieved. Thereafter the dosage can often be reduced by 1 mg each month. When higher doses have been started, they can be reduced by 5 mg every 1–2 weeks down to 20 mg/day, after which smaller steps (1–2.5 mg/day) should be made every 2–3 weeks. Immunomodulatory drugs such as methotrexate and azathioprine may allow further dose reductions. Short courses of GC for conditions such as asthma may be stopped abruptly if the total course is less than 14 days. With longer periods of treatment, the dose should be reduced gradually to allow the HPA axis to recover.

GLUCOCORTICOIDS IN RHEUMATOID ARTHRITIS: AN EXAMPLE

Glucocorticoids play a pivotal role in the management of rheumatoid arthritis (RA) and are used in various dosages at different disease stages. RA is therefore a useful example to discuss GC therapy in more detail.

KEY CONCEPTS

GC THERAPY IN RHEUMATOID ARTHRITIS

The risk–benefit ratio of low-dose GC has been shifted in the last few years:

- >> GC can now be considered as disease-modifying antirheumatic drugs, especially in early RA.
- >> Adverse effects of low-dose GC are less abundant and less severe than previously suggested, and some (e.g., osteoporosis) can be well managed.
- >> The goal of anti-rheumatic treatment in early RA is to induce remission of disease by aggressive management: GC are part of this aggressive strategy.

Low-dose maintenance therapy

In RA, GC therapy is often started and maintained low-dose, typically as additional therapy. GC in doses <10 mg are highly effective for relieving symptoms in patients with active RA: many patients are functionally dependent on this therapy and continue it long-term. A review of seven studies (253 patients in total) evaluating the symptomatic effect of GC in RA concluded that they are very effective when administered over about 6 months.²⁷ Improvement has been documented in all clinical parameters, including pain scales, joint scores, morning stiffness and fatigue, but also in acute inflammatory markers such as ESR and CRP. After 6 months of therapy the beneficial effects of GC seem to diminish; however, if therapy is then tapered and stopped, patients often experience an aggravation of symptoms during some months.

The disease-modifying properties of GC were first described in 1995, in a 2-year trial of 7.5 mg prednisolone in patients with RA of short/intermediate disease duration who also were treated with NSAIDs (95%) and disease-modifying antirheumatic drugs (DMARDs, 71%).²⁸ Since then, other trials have confirmed the potency of GC to retard joint damage. Today, GC are considered to have disease-modifying properties in early RA,²⁹ but it is less clear whether they can inhibit the progression of erosions in RA of longer duration.

Glucocorticoid pulse therapy

GC pulse therapy is used to treat some serious complications of RA and to induce remission in active disease, often when initiating second-line antirheumatic treatment. Pulse therapy with methylprednisolone 1 g per day dexamethasone 200 mg per day or equivalent, given intravenously for 1–3 days, was effective in most studies; the beneficial effect generally lasts for about 6 weeks, with large variations. It thus does not seem sensible to apply pulse therapy in active RA, unless the therapeutic strategy is changed (e.g. DMARD treatment introduced to maintain the remission induced by pulse therapy). A mitigated form of pulse therapy uses depot injection of 120 mg methylprednisolone acetate.

Intra-articular glucocorticoid injections

Intra-articular injections with GC are often used in RA. The benefit achieved depends on several factors, such as the joint treated (size, weightbearing or non-weightbearing), arthritis activity, the volume of synovial fluid in the joint, arthrocentesis (synovial fluid aspiration) before injection, choice and dose of GC preparation, injection technique, and whether the joint is rested.³⁰ It is recommended that intra-articular GC injections be repeated no more than once every 3–4 weeks, and no more than 3–4 times a year in a weightbearing joint to prevent GC-induced joint damage.

ADVERSE EFFECTS

Studies of GC toxicity tend to be retrospective and observational.³¹ This can make it difficult to differentiate unfavorable outcomes attributable to GCs from those occurring due to the underlying disease or other co-morbidities. Furthermore, there is a strong selection bias for GC use, as physicians are more inclined to use them in patients with more severe disease. Frequent, but less serious adverse effects (e.g., skin thinning, cushingoid appearance) may be of great concern to patients, whereas more debilitating toxicities such as osteoporosis, cataracts, and GC-induced hypertension may initially go unrecognized or be asymptomatic. The use of GCs at variable points in the disease course, limited data defining ‘threshold’ doses for particular adverse events, and toxicity reports covering a heterogeneous group of GC-treated diseases all further confound the interpretation of toxicity data.

Compared to other anti-rheumatic agents, GCs have a low incidence of short-term symptomatic toxicity and patients rarely discontinue therapy for these reasons. Despite over 50 years of use, robust data on the longer-term toxicities of glucocorticoids, from large randomized controlled trials with long-term follow-up, are sorely lacking. The commonest GC toxicities are summarized below, and reviewed in greater detail elsewhere.^{27,31}

Osteoporosis

Glucocorticoid-induced osteoporosis (GIOP) is the most devastating potential complication of prolonged GC therapy. Chronic GC treatment results in rapid and profound reductions in bone mineral density, with most bone loss occurring during the first 6–12 months of treatment.^{3,31} Cumulative dose appears to be the strongest predictor for changes in bone mineral density. Few studies, however, have been randomized controlled trials, and the mean GC doses used in individual studies vary. Although a decline in bone mineral density (BMD) is strongly correlated with fracture risk, and BMD is considered a good overall predictor of fracture risk, other factors, including GC-induced changes in bone turnover, micro-architecture, collagen content and cross-linking, are important determinants of fracture risk. The latter is greatly increased in long-term hypercortisolemic patients: 34–70% of patients suffer from low-trauma fractures within the first 5 years of therapy, the older age group being more affected than younger patients. However, it remains unclear whether using lower doses and/or careful follow-up reduces the risk of osteoporotic fracture.

GIOP initially affects trabecular bone, but with more chronic use cortical bone is also affected, at sites such as the femoral neck. Comparisons between different studies are difficult owing to the

differential timing of glucocorticoid initiation, variable dosing regimens, use of different bone mass measurement techniques, and disparities between the sites of measurement.

Precisely how GCs affect bone remains obscure. GCs decrease calcium absorption, increase renal calcium loss, diminish sex and growth hormone production, induce muscle wasting and modulate RANKL/OPG, NF- κ B and AP-1 signaling in bone.³² All of these changes lead to enhanced osteoclast function and lifespan, and hence to increased bone resorption. Consequently, markers of bone resorption are often increased in patients treated with GCs.^{28,33} However, reduced bone formation due to reduced osteoblast function is likely to be a more important effect of GCs on skeletal health. Oral doses of prednisone as low as 2.5 mg/day have been shown to suppress serum osteocalcin, a marker of bone formation. Histologically, mean wall thickness is reduced, reflecting the reduced amount of bone replaced in each remodeling unit. *In vitro*, osteoblasts and their precursors are highly GC responsive. Here, the predominant effect is to promote osteoprogenitor proliferation, lineage commitment and osteoblast differentiation, resulting in the formation of bone nodules of increased size and numbers. However, GCs also inhibit type I collagen expression, and reduce pre-osteoblastic replication. Finally, GCs promote apoptosis of osteoblasts and osteocytes. The inhibitory effects of GCs on bone formation may partly be due to down-regulation of IGF-I expression by osteoblasts.

Fortunately, we now have effective strategies for the prevention and treatment of GC-induced osteoporosis, using calcium, vitamin D and specific osteotropic agents (bisphosphonates or parathyroid hormone).

Osteonecrosis

Osteonecrosis has long been considered an important consequence of high-dose glucocorticoid use. In a Japanese study of femoral head osteonecrosis, 35% cases were related to GC treatment. Higher average dose may be a more important predictor of avascular necrosis of bone than cumulative dose. Osteonecrosis is particularly noted in SLE, but rarely occurs in RA patients receiving low-dose therapy, affecting less than 3% of patients. Osteonecrosis rarely occurs in SLE patients on prednisone doses <20 mg/day.

Myopathy

As with osteonecrosis, GC-induced myopathy is rare in patients receiving low-dose glucocorticoids. In small studies, myopathy appears more closely associated with fluorinated GC preparations such as triamcinolone than with prednisone. Notably, myopathy has been reported to occur after only 3 months’ treatment with triamcinolone 8 mg/day. In general, myopathy attributable to prednisone occurs after higher doses and longer durations of treatment.

Cardiovascular adverse effects

Although synthetic GCs have few mineralocorticoid effects, some studies suggest that high-dose therapy may promote fluid retention. However, several independent studies have shown no deleterious effects of long-term GC therapy on renal function, even when administered in medium to high doses to patients with impaired renal function. Despite increasing evidence that GCs do not induce fluid retention, hypertension is a well established adverse effect observed in about 20% of patients exposed to

exogenous GCs. Glucocorticoid-induced hypertension is dose related and might be less likely with medium- or low-dose therapy. Individual variation in susceptibility and other factors, such as the level of starting blood pressure, dietary salt intake, functional renal mass, associated diseases and drug therapy may also play a role. Patients with essential hypertension require closer surveillance of blood pressure and may need their anti-hypertensive regimen modified while on moderate- to high-dose GC therapy. In patients receiving <10 mg/day, age and elevated pre-treatment blood pressure may better explain significant hypertension than the use of GCs.

Another troublesome but very difficult-to-study potential toxicity of low-dose GCs is the development of premature atherosclerotic vascular disease. Increasing attention to the importance of accelerated atherosclerotic disease in RA and other inflammatory conditions has raised interesting questions about the role of chronic inflammation on the vascular endothelium. A threefold increase in atherosclerosis has been reported in RA patients treated with GCs compared to nonGC-treated patients, although the GC dose and other confounding factors were not reported. Studies evaluating the effects of GCs on lipids and atherosclerosis in RA patients have yielded mixed results. Observational studies of patients on long-term treatment with moderate to high doses of glucocorticoids for renal or cardiac allografts and asthma generally demonstrate elevations in total plasma cholesterol, low-density lipoprotein cholesterol (LDL-C), high-density lipoprotein cholesterol (HDL-C) and triglycerides. The effects of GCs on lipids seem to be dose dependent. In two studies in SLE patients, significant changes in lipid levels were seen only at prednisone doses >10 mg/day. In one report, moderate- to low-dose glucocorticoids (20 mg tapered to 5 mg over 3 months) had no significant adverse effect on lipoprotein levels if other risk factors were controlled. Other studies have even suggested that GCs may reverse unfavorable lipid changes. At present, the existing evidence does not show a strong association between low-dose glucocorticoids and cardiovascular disease in RA, even though atherosclerotic vascular disease is known to be accelerated in patients with Cushing's disease.

Dermatologic adverse effects

Even at low doses, skin thinning and ecchymoses are common adverse events with glucocorticoids. Cutaneous atrophy results from catabolic GC effects on keratinocytes and fibroblasts. Purpura and easy bruising in GC-treated patients is probably due to decreased vascular structural integrity. A cushingoid appearance is very troubling to patients, but is uncommon at doses below the physiologic range. One study reported facial fullness ('moon facies') in 13% of patients receiving 4–12 mg triamcinolone for up to 60 days. All these side effects are observed in over 5% of patients exposed to ≥ 5 mg prednisone equivalent for ≥ 1 year. The incidence of iatrogenic Cushing's syndrome is dose dependent and generally becomes evident after >1 month of GC therapy. Alternate-day therapy may reduce the incidence, although data supporting this concept are few. Glucocorticoid acne, hirsutism and striae are other undesirable dermatologic effects that occur even with lower doses.

Gastrointestinal adverse effects

Glucocorticoids are considerably less toxic to the upper gastrointestinal (GI) tract than NSAIDs. If GCs independently increase GI events (e.g., gastritis, ulceration, bleeding), the effect is slight, with estimated

relative risks varying from 1.1 (not significant) to 1.5 (marginally significant). There are also anecdotal reports of intestinal rupture, diverticular perforation, and pancreatitis attributed to low-dose GCs. Glucocorticoids are frequently used concurrently with NSAIDs in RA, and meta-analyses confirm that the combination of the two synergistically increases the risk of GI adverse events. In a large-scale study based on the UK General Practice Research Database, the risk of upper GI complications was 1.8 (95% CI, 1.3–2.4) times higher for GC users than for nonusers. The risk tended to be greater for higher GC doses, but the dose gradient was not statistically significant. The risk was >12 times higher for those taking both glucocorticoids and NSAIDs than for those not using either. No studies have yet looked at the GI effects of combining GCs with COX-2-selective NSAIDs.

Infectious diseases

Medium- to high-dose GC therapy, particularly when administered for prolonged periods, may increase the risk of serious infections requiring hospitalization or surgery. However, to our knowledge, no studies have explored the risk of infection in patients on lower doses. The risk of infection appears to be lessened with alternate-day therapy. A meta-analysis showed that infection rates were not significantly increased in patients on <10 mg/day prednisone or a cumulative dose of <700 mg.

In GC-treated patients, physicians should anticipate the risk of infections with both typical and atypical organisms, realizing that GCs may blunt the classic clinical features and delay diagnosis. *Pneumocystis jirovecii* infections can occur with doses as low as 16 mg/day of prednisone for 8 weeks and have been associated with increased risk in one series.³⁴ Herpes zoster is also more common in RA patients treated with immunosuppressive agents. In one analysis,³⁵ eight such patients developed zoster compared with only one control ($P<0.04$). However, it is difficult to separate the independent effects of GC use from those of other commonly used anti-rheumatic agents, such as methotrexate and anti-TNF- α agents. At present, the independent role of GCs in facilitating herpes zoster infection in RA patients remains uncertain.

Adverse effects on glucose metabolism

It is uncommon for frank diabetes mellitus to develop *de novo* as a result of GC therapy. However, patients with pre-existing diabetes will commonly have higher blood glucose levels while taking glucocorticoids. At doses of 1–7.9 mg/day prednisone, the odds ratio for hyperglycaemia is 1.8; this rises progressively to 7 when the dose of prednisone is ≥ 25 mg/day. The odds ratio of requiring therapy for hyperglycaemia is 1.7 during the first 45 days of GC use, falling to 1.3 between 46–90 days and to 1.1 thereafter. Ketoacidosis is very rare in GC-associated diabetes, as the gluconeogenic and glycogenic effects of GCs protect against this complication.

Adverse effects on the hypothalamopituitary axis

The prevalence of HPA insufficiency appears to depend on both the dose and the duration of GC treatment. High-dose therapy can result in marked and prolonged suppression of ACTH release and adrenal hyporesponsiveness after only 5 days. Spontaneous recovery of the HPA axis is the rule in patients on ≤ 5 mg/day prednisone; however, low doses (<7.5 mg/day) given for longer periods (e.g., 4–6 weeks) will also blunt

HPA responsiveness. Suppression of the HPA tends to be more pronounced if GCs are given twice daily instead of once daily. Glucocorticoid withdrawal syndrome is not clearly associated with HPA insufficiency, but presents as weakness and arthralgias. Indeed, difficulty in withdrawing patients from GCs is sometimes cited as a compelling reason for not initiating them. Despite these widely held sentiments, the issue of lower dose withdrawal has not been addressed in randomized controlled trials.

Neuropsychiatric adverse effects

Many patients suffering from RA report a slight increase in their overall sense of wellbeing when starting on low-dose GC therapy; this appears to be independent of improvements in disease activity. Symptoms of akathisia, insomnia, and depression are also occasionally observed during low-dose GC therapy. Memory impairment, particularly in older patients, can occur even at low doses and could relate to hippocampus-dependent functions. Daily split-dose therapy tends to be particularly troublesome, because the evening dose disrupts normal diurnal variations in endogenous GC levels and promotes sleep disturbances. True GC psychosis is distinctly uncommon at doses <20 mg/day prednisone.

Ophthalmologic adverse effects

Posterior subcapsular cataracts after prolonged GC use are well described. Some clinicians believe there is no minimal safe dose for this complication. Others note that cataracts rarely occur in patients taking <10 mg/day for <1 year. Cortical cataracts have also been associated with GC use. In addition to cataracts, GC-treated patients may develop increased intra-ocular pressure, which can cause minor visual disturbances. The development of frank glaucoma is rare, particularly with low-dose therapy, and tends only to affect patients already predisposed to the condition. GC-associated glaucoma tends to occur in families, suggesting a genetic basis. Highlighting a potential risk of even low-dose therapy, glaucoma may also occur with inhaled GCs.

NEW GLUCOCORTICOID RECEPTOR LIGANDS ON THE HORIZON

The various mechanisms of GC action provide interesting opportunities for developing optimized GCs and GC-receptor ligands, which are reviewed below. More detailed information is available elsewhere.^{1, 31, 36}

SELECTIVE GLUCOCORTICOID RECEPTOR AGONISTS (SEGRAS)

The existence of the genomic component mechanisms of transactivation and transrepression provides a foundation for developmental research into GC-receptor ligands that cause predominantly transrepression but not transactivation. This research is based on the assumption that the anti-inflammatory properties of GCs are mostly due to repression of AP-1- and NF- κ B-stimulated synthesis of inflammatory mediators, whereas most of their adverse effects are associated with transactivation of genes involved in metabolic processes. Investigators have therefore sought novel GCR ligands with high repression but low transactivation

activity. One such compound, A276575, exhibits a high affinity for the GCR and potently represses IL-1 α -induced IL-6 production, similarly to dexamethasone. However, unlike dexamethasone, A276575 induces little aromatase activity. Other novel nonsteroidal GCR ligands are being developed which possess high repression activities against inflammatory mediator production, but have lower transactivation activities than traditional GCs. Substances that cause a receptor conformation preferring a GCR/protein interaction and not a GCR/DNA-binding-dependent mechanism are now being called 'dissociated glucocorticoids' or selective glucocorticoid receptor agonists (SEGRAs). At present it cannot be reliably predicted whether SEGRAs will prove clinically useful, as 'improved glucocorticoids'. However, these novel developments are very interesting; further *in vivo* investigations and preliminary clinical trials are needed to define the safety/efficacy profile of SEGRAs.

NITRO-STERIODS

Recent experimental observations prompt assessment of the clinical impact of another new class of glucocorticoid drugs, nitro-steroids, on RA and inflammatory bowel disease. Nitro-steroids are able to release low levels of nitric oxide (NO) and are endowed with enhanced anti-inflammatory properties and fewer unwanted effects. The prototype of these new steroids, 21-NO-prednisolone (NCX-1015), is much more potent than prednisolone in models of acute and chronic inflammation, including collagen II-induced arthritis. In contrast, in an *in vitro* assay of bone resorption NCX-1015 did not activate primary osteoclast activity, whereas prednisolone did. This lack of effect of NCX-1015 was chiefly due to NO. It has been suggested that post-translational modification of GCR (tyrosine nitration) by NCX-1015 may explain its enhanced anti-inflammatory activity. Moreover, NCX-1015 potently stimulates IL-10 production, suggesting that nitro-steroids induce regulatory T cells that negatively modulate inflammation. However, more studies are needed to confirm that nitro-steroids will be effective as anti-inflammatory agents in clinical practice.

LONG-CIRCULATING LIPOSOMAL GLUCOCORTICIDS

As previously discussed, the anti-inflammatory efficacy of GCs can be improved by the additional benefits of nongenomic actions at high GC concentrations. This has led to the successful use of long-circulating liposomal GCs. In rats with experimental autoimmune encephalitis, GC-containing liposomes accumulate at sites of inflammation, reaching ultra-high concentrations ($> 10^{-5}$ mol/L for ≥ 18 hours). These liposomes may thus be therapeutically superior to conventional intravenous high-dose GC therapy, as evidenced by their successful use in rats with adjuvant-induced arthritis. A single injection of 10 mg/kg liposomal prednisolone phosphate resulted in complete remission of the inflammatory response for almost a week. In contrast, the same dose of unencapsulated prednisolone phosphate did not reduce inflammation, and only a slight effect was observed after repeated daily injections. One may conclude that preferential delivery of GC to the site of inflammation leads to very high GC concentrations at the inflamed joint, but lower plasma concentrations with perhaps a lower rate of side effects. These are very promising developments which exploit the broad spectrum of therapeutically relevant genomic and nongenomic GC actions preferentially at the site of inflammation.

In conclusion, recent research has greatly increased our knowledge of conventional GCs as the best anti-inflammatory agents currently available. In particular, new findings on the effects of occupation of cytosolic GCRs on intracellular signaling, transcription processes and gene expression, and on the existence of membrane-bound glucocorticoid receptors as well as the information on dose–effect relationships, have stimulated intensive research activity aimed at bringing this increased knowledge from scientific research into clinical practice as quickly as possible. The new GCR ligands and liposome encapsulation are very promising approaches that will hopefully soon be available in clinical practice to improve the risk–benefit ratio of GC therapy and the wellbeing of patients.

Nonsteroidal anti-inflammatory drugs

Maryam Shahbaz-Samavi, Frank McKenna

88

The earliest evidence of the use of willow bark as a medicinal agent is documented in Chinese records from over 7000 years ago. Hippocrates (460–377 BC) described the use of powder made from the bark and leaves of the willow tree to help heal headaches, pains, and fevers. In 1826 Brugnatelli and Fontana obtained a highly impure form of bitter-tasting yellow crystals from willow bark, but working separately 2 years later, Johann Buchner, professor of pharmacy at the University of Munich, Germany, isolated a tiny amount of crystalline material and called it salicin. By 1829, Henri Leroux had improved the extraction procedure to obtain about 30 g from 1.5 kg of bark. In 1838 Raffaele Piria, working at the Sorbonne in Paris, split salicin into a sugar and salicylaldehyde and converted the latter, by hydrolysis and oxidation, to an acid of crystallized colorless needles, which he named salicylic acid. However, salicylic acid was poorly tolerated. In 1853 Charles Frederic Gerhardt created acetylsalicylic acid by buffering salicylic acid with sodium (sodium salicylate) and acetyl chloride, but it was not developed. The method was rediscovered and modified in 1897 by Felix Hoffmann and his colleagues, working for Bayer. Hoffmann's father had arthritis and was intolerant of salicylates but found acetylsalicylic acid to be more effective and well tolerated. Bayer decided to market the compound which they named aspirin from the 'a' in acetyl chloride, the 'spir' in *Spiraea ulmaria* (the plant from which they derived the salicylic acid), and 'in' was a familiar ending for medicines. Aspirin was patented on March 6th, 1889 and in 1915 became the first mass-produced tablet in medicine. Over the last century there have been over 20 other similar anti-inflammatory analgesics developed and licenced, the class being named nonsteroidal anti-inflammatory drugs (NSAIDs).

BIOCHEMISTRY AND PHARMACOLOGY

All NSAIDs are completely absorbed, have negligible first-pass hepatic metabolism, are tightly bound to albumin, and have small volumes of distribution. Half-lives of the NSAIDs vary from about 2 hours to more than 24 hours, although the duration of biological effect may be significantly longer than the plasma half-life. Patients with hypoalbuminemia

may have a higher free serum concentration of the drug. There is a clear individual variation in response to NSAIDs and their toxic effects. These differences have been ascribed to differences in absorption, distribution, and metabolism. In addition, numerous mechanisms of action have been ascribed to the NSAIDs.

Vane established in the 1970s that a major effect of NSAIDs is to inhibit cyclooxygenase (COX or prostaglandin synthase: PGHS), thereby impairing the ultimate transformation of the unsaturated fatty acid arachidonic acid, derived from cellular phospholipids, to prostaglandins, prostacyclin, and thromboxanes (Fig. 88.1).¹ The extent of enzyme inhibition varies among the different NSAIDs, although there are no studies relating the degree of COX inhibition with anti-inflammatory efficacy in individual patients. Two related isoforms of the COX enzyme were discovered in the 1980s: COX-1 (PGHS-1) and COX-2 (PGHS-2).² The most important differences between the two isoforms are the regulation and expression of the enzymes in different tissues.

COX-1 is variably expressed in most tissues. It has been described as a 'housekeeping' enzyme, regulating normal cellular processes such as gastric cytoprotection, vascular homeostasis, platelet aggregation, and renal function; its production is stimulated by hormones or growth factors.

COX-2 is constitutively expressed in the brain, kidney, bone, and probably in the female reproductive system, but it is not expressed in normal gastrointestinal mucosa. It is also expressed at other sites during inflammation or in mitotic tissue, and experimentally in response to mitogenic stimuli. Both COX isoforms are regulated by physiological stimuli. In the human kidney COX-2 mRNA is found in normal kidney and increased in certain pathological conditions, including diabetic nephropathy, hypertension, and heart failure.³ COX-2 is also expressed in malignant cells and a number of studies have found a beneficial therapeutic effect from COX-2 inhibition, most notably in reducing malignant change in adenomatous colonic polyps. There are important differences in the regulation and expression of these enzymes in various tissues. One distinguishing characteristic of COX-2 is that its expression is inhibited by glucocorticoids, which may contribute to the anti-inflammatory effects of glucocorticoids.

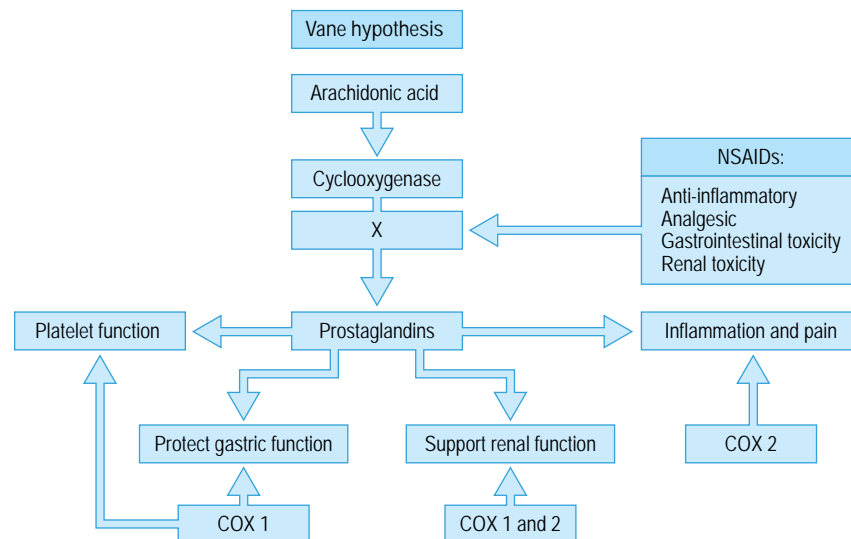

Fig. 88.1 The Vane hypothesis of the mode of action of nonsteroidal anti-inflammatory drugs (NSAIDs). COX, cyclooxygenase.

Fig. 88.2 The chemical structure of licenced cyclooxygenase-2 (COX-2) inhibitors.

It is unclear whether there are other biologically active COX enzymes. COX-3 has been described^{4,5}; this is a splice variant derived from the COX-1 gene with an additional peptide sequence derived from intron I. COX-3 appears to be expressed at a high level in the central nervous system, with transcripts for this splice variant accounting for 5% of COX mRNA, although at present it is uncertain whether this enzyme is expressed in humans.

Differences in the extent to which a particular NSAID inhibits an isoform of COX can affect both its activity and toxicity. Most traditional NSAIDs are nonselective inhibitors of both COX-1 and COX-2. Because

the toxicity of NSAIDs on the gastrointestinal tract is largely related to the inhibition of COX-1, highly selective COX-2 inhibitors have been developed that do not inhibit COX-1 at therapeutic doses (Fig. 88.2). Celecoxib (Celebrex) and rofecoxib (Vioxx) were initially approved for use in rheumatoid arthritis, osteoarthritis, and acute pain. Etoricoxib (Arcoxia), valdecoxib (Bextra), and lumiracoxib (Prexige) have subsequently been licenced. Rofecoxib was withdrawn worldwide by the manufacturer due to an increased risk of adverse cardiovascular events. Valdecoxib was also withdrawn from the US and European Union markets in April 2005 because of a small but increased risk of Stevens–Johnson syndrome,

KEY CONCEPTS

Two distinct cyclooxygenase (COX) enzymes exist:

- >> COX-1 is constitutively expressed in most tissues, and is involved in homeostasis and 'housekeeping' functions
- >> COX-2 is constitutively expressed in brain, bone, and kidney, but not in normal gastrointestinal tract. It is induced by cytokines, endotoxin, tumor promoters, growth factors, and gonadotropins

although parecoxib, a prodrug of valdecoxib, remains available for clinical use. These compounds have been shown to provide comparable analgesia to the nonselective NSAIDs in patients with pain and arthritis, with a reduced risk of gastroduodenal toxicity. Although some older NSAIDs are also relatively selective for COX-2 at low doses (e.g., etodolac inhibits the COX-2 isoform 10 times more than COX-1), it is unclear whether this avoids inhibition of COX-1 at therapeutic doses. Endoscopic studies with COX-2 inhibitors have found an incidence of ulceration comparable to placebo. However, although selective COX-2 inhibition may produce less gastric toxicity, there has been concern that COX-2 inhibition may enhance injury in inflamed tissue and delay healing of gastric erosions or ulcers,⁶ an observation that may explain why COX-2 inhibitors have been associated with peptic ulceration.

NONPROSTAGLANDIN-MEDIATED EFFECTS

Although aspirin (the only acetylated NSAID) is not thought to have effects other than those related to inhibition of prostaglandin synthesis, several nonprostaglandin-mediated mechanisms of action have been postulated to explain the actions of the nonacetylated salicylates; these mechanisms may also apply, to a varying degree, to the nonsalicylate NSAIDs. Some of these effects appear to be related to the physicochemical property of NSAIDs that enables them to insert into biological membranes and disrupt important interactions necessary for cell function (e.g., transmembrane anion transport, oxidative phosphorylation, and uptake of arachidonate). Neutrophil function is inhibited by nonacetylated salicylates and other nonsalicylate NSAIDs *in vitro*. As an example, NSAIDs interfere with the neutrophil–endothelial cell adherence that is critical for the ability to respond to inflammation. NSAIDs decrease the expression of L-selectin, which removes a crucial step in the migration of granulocytes to sites of inflammation. The role of these nonprostaglandin-mediated processes in clinical inflammation remains unclear.

NSAIDs have also been shown to inhibit NF- κ B-dependent transcription *in vitro*, leading to inhibition of inducible nitric oxide synthetase (iNOS). Nitric oxide synthetase, once induced by cytokines and other proinflammatory mediators, produces nitric oxide in large amounts, thereby leading to increased inflammation (including vasocongestion, cytotoxicity, and vascular permeability). Therapeutic levels of aspirin inhibit expression of iNOS and the subsequent production of nitrite *in vitro*, whereas sodium salicylate, indometacin, and acetaminophen (paracetamol) have no such effects at pharmacological concentrations.

KEY CONCEPTS

The efficacy of both nonsteroidal anti-inflammatory drugs (NSAIDs) and cyclooxygenase-2 (COX-2) inhibitors is mediated by the reduction of inflammatory prostaglandins produced following the action of COX-2 on arachidonic acid

Nonselective NSAIDs inhibit both COX-1 and COX-2, but at therapeutic concentration COX-2 inhibitors do not inhibit COX-1

NSAIDs and COX-2 inhibitors are analgesics with anti-pyretic and weak anti-inflammatory effects

Gastrointestinal toxicity is predominantly a consequence of the inhibition of COX-1, whereas renal toxicity results from inhibition of both COX-1 and COX-2

EFFICACY**ANTI-PYRETIC EFFECT**

The synthesis of prostaglandin E₂ (PGE₂) depends on the constitutively expressed COX enzyme, and inhibitors of either COX-1 or COX-2 are potent anti-pyretics. There is a direct correlation of the anti-pyretic potency of various drugs with the inhibition of brain COX. Acetaminophen is a poor inhibitor of COX in peripheral tissue and has no significant anti-inflammatory activity; however, acetaminophen is oxidized in the brain by the cytochrome p450 system, and the oxidized form inhibits COX, which may explain why there is no difference between oral aspirin and acetaminophen in reducing fever in humans. NSAIDs such as naproxen or ibuprofen are also excellent anti-pyretics. However, there appears to be no role for PGE₂ in normal thermoregulation, as chronic use of aspirin or NSAIDs in arthritis does not reduce normal core body temperature.

OSTEOARTHRITIS

NSAIDs are effective in the symptomatic relief of osteoarthritis but there is considerable individual variation in response, with some patients experiencing little or no response to treatment. A meta-analysis of 10 randomized control trials demonstrated that acetaminophen was an effective treatment for osteoarthritis but was inferior to NSAIDs.⁷ In cross-over studies between acetaminophen and NSAIDs (Fig. 88.3) or coxibs, the majority of patients with osteoarthritis preferred the anti-inflammatory drugs.^{8–10} A minority of patients prefer acetaminophen but unfortunately there are no clinical features that predict which treatment is likely to be most effective. Studies with COX-2 inhibitors have found similar efficacy to nonselective NSAIDs but with better tolerability.^{11,12} The American College of Rheumatology treatment guidelines for osteoarthritis support the use of NSAIDs in conjunction with nonpharmacological measures for some acetaminophen-naïve patients, particularly those with more severe pain.¹³ EULAR (European League against Rheumatism) guidelines recommend NSAIDs for patients with osteoarthritis of the knee whose pain is inadequately relieved with acetaminophen.¹⁴

Fig. 88.3 Preference of diclofenac versus acetaminophen (paracetamol) in a cross-over study in patients with osteoarthritis (OA). (Data from Pickavance L, Griffiths G, McKenna F. *Br J Rheumatol* 1995; 34: (suppl 1): 137.

RHEUMATOID ARTHRITIS

NSAIDs are effective symptomatic therapy for rheumatoid arthritis. However, although they have both analgesic and anti-inflammatory properties, they do not affect objective measures of the inflammatory response and do not alter disease outcomes. Appropriate initial therapy of patients with mild disease consists of an NSAID at full therapeutic dose. Most physicians and patients prefer initiating therapy with an NSAID or COX-2 inhibitor rather than a salicylate, as they are usually better tolerated and have a longer duration of action.

The dose of NSAIDs is titrated to the optimum tolerated level and continued for at least 2 weeks. Therapeutic trials of individual NSAIDs continue until the patient appears to have achieved adequate control of symptoms with minimal side effects. If NSAIDs are combined, there is an increased risk of gastrointestinal toxicity, without any additional therapeutic benefit. NSAIDs will only partially improve symptoms in those with active disease and do not prevent the development of erosive disease. Thus, when there are signs of persistent synovitis (e.g., swollen joints, tender joints, or elevated acute-phase response (erythrocyte sedimentation rate or C-reactive protein)), it is recommended that disease be controlled with intra-articular or intramuscular corticosteroids and one or more disease-modifying anti-rheumatoid drugs (DMARDs) be added.

SYSTEMIC LUPUS ERYTHEMATOSUS

NSAIDs are generally effective for musculoskeletal complaints and mild serositis. COX-2-selective inhibitors may also be effective in such patients. Although celecoxib contains a benzenesulfonamide moiety and should be used with caution in those with a known sulfonamide allergy, celecoxib has been used in systemic lupus erythematosus patients, even those with "sulfa" allergy, without precipitating any allergic response. The potential for allergic responses to NSAIDs is discussed below.

SPONDYLOARTHRITIS

Symptoms of acute arthritis or enthesopathy from reactive arthritis, including Reiter's disease, usually respond to NSAIDs but high doses may be needed. NSAIDs are often very effective in relieving the pain and stiffness from ankylosing spondylitis. Although

indometacin was thought to be the most effective NSAID for ankylosing spondylitis, there is little evidence that any single compound is superior in efficacy. The selection of a particular NSAID to treat ankylosing spondylitis should therefore reflect the presence or absence of risk factors for adverse effects with specific NSAIDs.

CARDIOVASCULAR PROPHYLAXIS

Aspirin has proven efficacy for secondary prevention of cardiovascular disease, and, in selected patients, for primary prevention. With respect to primary prevention, it has been suggested that low-dose aspirin prophylaxis is warranted in patients with an estimated 10-year risk of cardiovascular disease of 6–10%. Aspirin differs from other NSAIDs in binding permanently in circulating platelets. Since other NSAIDs only inhibit platelet function temporarily and they compete with aspirin for the binding site, they should not be ingested with aspirin.¹⁵ This is not a concern with COX-2 inhibitors as they do not bind to platelets. However, following the withdrawal of rofecoxib because of potential cardiac toxicity, there has been concern that other NSAIDs and COX-2 inhibitors may actually increase the risk of cardiac disease (see below).

CEREBROVASCULAR ACCIDENT

The effectiveness of aspirin for preventing ischemic stroke and cardiovascular events is supported by a meta-analysis of 195 randomized clinical trials comparing anti-platelet therapy, primarily aspirin, with placebo in the prevention of stroke, myocardial infarction (MI), and vascular death among high-risk patients with some vascular disease or other condition, implying an increased risk of occlusive vascular disease.¹⁶ Patients treated with anti-platelet therapy (primarily aspirin) had a 25% relative risk reduction in nonfatal stroke compared with placebo. Among the subset of patients with prior cerebrovascular disease (transient ischemic attack or stroke), anti-platelet therapy reduced the risk of secondary stroke, MI, or vascular death by 22%; the absolute benefit was 36 events prevented per 1000 patients treated for 29 months. The benefit of anti-platelet therapy was independent of sex, age, diabetes, or hypertension.

Stopping anti-platelet therapy in high-risk patients may itself increase the risk of stroke. Given the apparent equivalent benefit of different doses of aspirin for ischemic stroke prevention, and the increased risk of bleeding complications with higher-dose aspirin, a dose of 50–81 mg/day when using aspirin for the secondary prevention of ischemic stroke seems reasonable.

NSAIDs AND CANCER

Most epidemiological studies suggest that aspirin use reduces the risk of colorectal cancer by approximately 40–50%.¹⁷ A similar reduction in colorectal adenoma risk is also observed, suggesting that the benefit may occur at early stages of carcinogenesis. Consistent with this pattern, some, but not all, data indicate that up to 10 years of use may be required for a significant effect on colorectal cancer incidence. Nonaspirin NSAIDs, including COX-2-selective inhibitors, appear to have a similar anti-cancer benefit. Nonetheless, the clinical implications of these findings remain unclear because of increased toxicity related to chronic aspirin and NSAID use and the proven efficacy of alternative prevention strategies, particularly colonoscopic screening.¹⁸ The overall risks and benefits of prolonged NSAID use, as well as the risk profile of the individual patient, should be considered before making individual recommendations.

NSAIDs IN ALZHEIMER'S DISEASE

Some epidemiological studies have suggested that NSAIDs protect against the development of Alzheimer's disease.¹⁹ However the results have been conflicting and may be due in part to the timing and duration of NSAID use, and to differences in tracking NSAID use. In addition, all of the studies of this issue are observational studies, which are subject to various forms of bias. Apart from an effect on risk of Alzheimer's disease, long-term use of NSAIDs has also been associated with preservation of cognitive function and prevention of early cognitive decline, although this effect has not been uniform. Use of NSAIDs has also been associated with a decreased incidence of Parkinson's disease, another important cause of dementia. However, at present there are insufficient data to recommend this treatment for prevention of dementia.

TOXICITY

INTOXICATION

NSAIDs are among the most common classes of medications prescribed in the USA. Despite the high rates of acute ingestion, few patients experience poor outcomes, and most require no medical intervention or supportive care alone. Symptoms and signs in NSAID intoxication are generally nonspecific. The most common symptoms are nausea, vomiting, drowsiness, blurred vision, and dizziness. NSAID ingestion of less than 100 mg/kg is unlikely to cause significant symptoms; ingestions greater than 400 mg/kg can cause severe symptoms. Renal failure and renal papillary necrosis are rare but do occur, most commonly in patients with decreased effective arterial volume, age-related underlying renal dysfunction, or massive overdose. Acute central nervous system toxicity related to NSAID use shows a variety of clinical manifestations, ranging from mild drowsiness to seizure or coma.

GASTROINTESTINAL TRACT (FIG. 88.4)

The pathogenesis of symptomatic peptic ulcer disease caused by exposure to NSAIDs is mainly a consequence of systemic inhibition of gastrointestinal mucosal COX activity. Even intravenous or intramuscular administration of aspirin or NSAIDs can cause gastric or duodenal ulcers in animals and humans. Many mucosal functions are altered by

endogenous or exogenously administered PGs: this may explain the mucosal protective effects of PGs. Combined mucus and bicarbonate secretion forms an alkaline layer on the surface of the gastric mucosa, which retards diffusion of acid pepsin from the lumen into the mucus. Gastric and duodenal injury by acid and pepsin occurs when these protective functions are compromised and may lead to gastric and/or duodenal ulcer formation with associated risks of bleeding, perforation, or obstruction. Some of the cytoprotective mechanisms of PGs include stimulation of glycoprotein (mucin) secretion, stimulation of bicarbonate secretion, stimulation of phospholipid secretion, increased epithelial cell migration towards the luminal surface (restitution), enhanced epithelial cell proliferation, and enhancement of mucosal blood flow. This last effect may control a number of the other mechanisms.

Generation of nitric oxide may be a key intermediate in cytoprotection.²⁰ Similar to the role of COX-1, constitutive nitric oxide synthase (NOS) is important in the maintenance of an intact mucosal lining. Two enzymes contribute to the basal, constitutive NOS activity: neuronal NOS (nNOS, type I) and endothelial NOS (eNOS, type III). The cytoprotective mechanisms of nitric oxide parallel PG effects and include mediation of the release of gastric mucus, stimulation of fluid secretion, maintenance of epithelial barrier function, and enhancement of mucosal blood flow.

While inhibition of COX-1 is the major mechanism by which NSAIDs produce gastric injury, mediators besides PGs (and nitric oxide) may also be involved. For example, interference with factors that mediate restitution or adaptive protection may contribute to mucosal injury. Adaptive protection refers to the observation that mild gastric irritants induce enhanced cytoprotection. COX-1, COX-2, and nitric oxide as well as various growth factors, including epidermal growth factor and transforming growth factor (TGF)- β and TGF- α , appear to participate in these adaptive processes.²¹ NSAIDs probably interfere with growth factors and other mediators responsible for restitution and adaptive protection, further contributing to their toxicity.

The role of *Helicobacter pylori* (HP) infection in NSAID-induced gastritis or ulcer formation is complex.²² Although the incidence of ulceration in some studies appears to be similar in HP-positive and -negative patients, other studies have found a reduction in NSAID ulceration after HP eradication. There are also some data indicating that the risk of ulcer hemorrhage may be increased in HP-positive patients.

The risk of developing significant NSAID-induced gastrointestinal bleeding or perforation due to a peptic ulcer has been evaluated in multiple studies.²³ The duration of therapy is important. Administration of NSAIDs for short periods (less than 1 week) in healthy people is unlikely to result in any significant gastroduodenal toxicity. In contrast, longer duration of therapy is associated with an increased risk of complications. Gastroduodenal toxicity may develop even in patients taking low doses of NSAIDs (such as for cardiovascular prophylaxis), which, despite the low dose, can be associated with a significant decrease in gastric mucosal prostaglandin concentrations. Gastric ulceration from NSAIDs is often silent (Fig. 88.5). Several other factors are associated with increased risk of gastroduodenal toxicity and complications such as bleeding from NSAIDs. The most important risk factor is age (Fig. 88.6). The risk increases above the age of 60 with an approximately 10-fold risk in those aged over 75 years.²⁴ A past history of peptic ulceration or NSAID toxicity, the presence of comorbid diseases, a higher dose of NSAID, or concurrent use of glucocorticoids or anticoagulants all increase the risk of ulceration. Overall the annual risk of admission from regular NSAID therapy is approximately 1% per annum. Among those admitted, mortality is approximately

10%, largely in the elderly and frail. The risk is reduced but not eliminated by prescribing COX-2 inhibitors.

The CLASS (celecoxib), VIGOR (rofecoxib) and TARGET (lumiracoxib) studies demonstrated an approximate threefold reduction in the incidence of gastrointestinal complications compared with nonselective NSAIDs, although in both the CLASS and TARGET studies this difference was largely eliminated with co-prescription of low-dose aspirin. (Patients taking low-dose aspirin were excluded from the VIGOR

study.) However, none of these studies included a placebo comparator. A retrospective observational study in elderly patients in Ontario²⁵ found the incidence of gastrointestinal complications related to celecoxib was similar to an age- and gender-matched control group; there was a small but significantly increased incidence from rofecoxib but this was less than the rate seen with either diclofenac/misoprostol combination (Arthrotec) or other nonselective NSAIDs (Fig. 88.7).

The distal small bowel and colon are also susceptible to the deleterious effects of NSAIDs.^{26,27} The ileocecal region is a potential site for a variety of NSAID-induced injuries, including erosions, ulcers, strictures, perforation, and the formation of diaphragms, which can lead to bowel obstruction. NSAIDs can also lead to colitis resembling inflammatory bowel disease, exacerbate pre-existing inflammatory bowel disease, or complicate diverticular disease (i.e., perforation or bleeding). Elderly people and those on long-term NSAID therapy appeared to be at highest risk. Emerging data from video endoscopic studies indicate that there is a significantly greater risk of small-bowel lesions from NSAIDs than COX-2 inhibitors²⁸ and the risk is not reduced by co-prescription of proton pump inhibitors.

The potential gastroduodenal sparing effect of selective COX-2 inhibitors may be reduced or eliminated by concurrent low-dose aspirin therapy for primary or secondary prevention of cardiovascular or cerebrovascular disease. This may be directly related to the effect of aspirin, which blocks COX-1 in the gastrointestinal tract. In the CLASS and TARGET studies similar rates of ulcers and ulcer complications were noted among those receiving the COX-2 inhibitors plus low-dose aspirin as among patients receiving a nonselective NSAID plus aspirin. Thus, patients receiving both aspirin and a selective COX-2 inhibitor may also require prophylactic anti-ulcer therapy if they are at risk for gastroduodenal toxicity.

Fig. 88.5 Incidence of dyspeptic symptoms in patients with either a normal upper gastrointestinal endoscopy or a gastric ulcer whilst taking regular nonsteroidal anti-inflammatory drugs (NSAIDs). (Data from Mason J, McKenna F. *Ann Rheum Dis* 2002; Suppl. 2: 257.)

RENAL

NSAIDs can induce two different forms of acute renal failure: hemodynamically mediated and acute interstitial nephritis (which is often accompanied by the nephrotic syndrome). The former and perhaps the

Fig. 88.6 Risk factors for nonsteroidal anti-inflammatory drug (NSAID) ulcer complications. OR, odds ratio. (Data from Hansen JM, Hallas J, Lauritsen JM, et al. Non-steroidal anti-inflammatory drugs and ulcer complications: a risk factor analysis for clinical decision-making. *Scand J Gastroenterol* 1996; 31: 126–130.)

Fig. 88.7 The rate of upper gastrointestinal (GI) complications in Ontario in elderly patients prescribed nonsteroidal anti-inflammatory drugs (NSAIDs) or cyclooxygenase-2 (COX-2) inhibitors. (Data from Mamdani et al. *Br Med J* 2002; 325: 624–629.²⁵)

CLINICAL PEARLS

- Gastric ulceration from nonsteroidal anti-inflammatory drugs (NSAIDs) is common and often silent
- Complications from NSAID ulceration are more common in the elderly and frail
- Cyclooxygenase-2 inhibitors are associated with a significant reduction in gastrointestinal complications
- A life-threatening gastrointestinal complication from NSAIDs may occur after as little as 7 days' treatment

latter are directly related to the reduction in prostaglandin synthesis induced by NSAIDs.²⁹

Although renal prostaglandins are primarily vasodilators, they do not play a major role in the regulation of renal hemodynamics in normal subjects, since the basal rate of prostaglandin synthesis is relatively low. In contrast, the release of these hormones (particularly prostacyclin and PGE₂) is increased by underlying glomerular disease, renal insufficiency, hypercalcemia, and the vasoconstrictors angiotensin II and norepinephrine. The secretion of these latter hormones is increased in states of effective volume depletion, such as heart failure or cirrhosis, and in true volume depletion due to gastrointestinal or renal salt and water losses. Vasodilator prostaglandins act to preserve renal blood flow and glomerular filtration rate by relaxing preglomerular resistance. This is particularly important with effective volume depletion, in which the prostaglandins antagonize the vasoconstrictor effects of angiotensin II and norepinephrine. In glomerular disease, however, the increase in prostaglandin production seems to maintain the glomerular filtration rate even in the presence of a reduction in glomerular capillary permeability.

In some patients inhibition of prostaglandin synthesis with an NSAID may therefore lead to reversible renal ischemia, a decline in glomerular hydraulic pressure, and acute renal failure. The rise in the plasma creatinine

concentration is often seen within the first 3–7 days of therapy, the time required to achieve steady-state drug levels and maximum inhibition of prostaglandin synthesis. The selective COX-2 inhibitors may also precipitate acute renal failure in some patients.³⁰ How frequently this occurs compared to the nonselective NSAIDs is unclear but it is advisable to consider COX-2 inhibitors to have a similar risk of nephrotoxicity to nonselective NSAIDs.

Acute interstitial nephritis may occur with any nonselective NSAID. There have also been case reports of selective COX-2 inhibitors being associated with this pattern of injury. The mechanism is uncertain but it is possible that COX inhibition results in the preferential conversion of arachidonic acid to leukotrienes, which can then activate helper T cells. Patients usually present with hematuria, pyuria, white cell casts, proteinuria, and an acute rise in plasma creatinine concentration. Fever, rash, and eosinophilia are uncommon. Spontaneous recovery generally occurs within weeks to a few months after therapy is discontinued. Corticosteroids are sometimes used empirically if the renal failure persists for 1–2 weeks after NSAID withdrawal, although the benefit of such treatment is not established. After recovery patients should avoid subsequent administration of NSAIDs as relapse may occur with rechallenge.

CARDIAC FAILURE

NSAIDs may cause an exacerbation of heart failure. The probable cause is an increase in afterload resulting from reduction in vasodilatory prostaglandins such as prostacyclin, plus the renal effect of salt and water retention. In addition, NSAIDs may partially or totally reverse the beneficial effect of angiotensin-converting enzyme inhibition, reversing the improvements in cardiac output, and may also blunt the renal effects of diuretics, causing a further exacerbation of symptoms. There may be differences between drugs. The combined risk of death and recurrent congestive heart failure was higher in patients prescribed NSAIDs or rofecoxib than in those prescribed celecoxib in a population-based retrospective cohort study of 2256 patients aged 66 or more, who were prescribed celecoxib, rofecoxib, or an NSAID after an index admission for congestive heart failure.³¹ However, the risks of death and recurrent congestive heart failure, combined and separate, were similar between patients prescribed NSAIDs and rofecoxib.

MYOCARDIAL INFARCTION

The benefit of platelet inhibition by aspirin for the secondary and, in selected patients, primary prevention of cardiovascular disease has been clearly demonstrated. However, concerns were raised that anti-inflammatory drugs may increase the risk of cardiac events following the results of the VIGOR trial, with the observation of a significant increase in cardiac events in those taking rofecoxib compared with naproxen. Although analysis of the CLASS and TARGET studies did not find any significant difference in cardiac events between either celecoxib or lumiracoxib and the comparator nonselective NSAIDs, the results of the VIGOR study raised the question whether selective COX-2 inhibition may increase the risk of MI or whether the anti-platelet effect of naproxen reduced the risk of cardiac events. However, most studies have not found a cardio-protective effect from naproxen.³² In addition, in placebo-controlled studies evaluating the benefit of COX-2 inhibitors in patients with colonic polyps, there was an increased incidence of events with rofecoxib in standard-dose,³³ and also in one study with high-dose celecoxib.³⁴ These studies did

Fig. 88.8 The incidence of myocardial infarction in a prospective study in California in patients taking nonsteroidal anti-inflammatory drugs (NSAIDs) or cyclooxygenase-2 (COX-2) inhibitors. FDA, Food and Drug Administration. Data from Graham DJ et al, *Lancet* 2005;365:475-81.

not have an NSAID comparator and the number of events were small but indicated the need for further studies.

A number of observational studies have now been undertaken with similar findings. The results from a large prospective observational study conducted by the Food and Drug Administration (FDA) in California are typical (Fig. 88.8). They found a threefold risk of MI with high-dose rofecoxib, and a small but significant increased risk with a number of other NSAIDs but not from celecoxib.³⁵ Although the risk from celecoxib may have been underestimated, these data do not support the hypothesis that COX-2 inhibition increases the risk of MI any more than other NSAIDs. The risk from rofecoxib, particularly in high dose, appears to be specific to that compound. The mechanism may be related to a greater effect on salt and water retention and blood pressure, but there may be other mechanisms. As a result of these and other data, the FDA placed a black box warning on all NSAIDs and COX-2 inhibitors related to the small but significant risk of cardiac disease with these compounds.

HEMATOLOGICAL

The anti-platelet effects of NSAIDs are due to inhibition of COX-1 and decreased production of thromboxane A₂, which is released by platelets in response to a number of agonists, amplifying the platelet response and leading to aggregation. COX-2 is not expressed in platelets and COX-2 inhibitors do not have any effect on platelet function. NSAIDs should be avoided in patients with pre-existing platelet defects, in patients with thrombocytopenia, and perioperatively.

HEPATIC

Mild elevation of serum aminotransferases (transaminases) is commonly associated with NSAID use, particularly with diclofenac, but liver failure is quite rare. Diclofenac has been reported to cause clinical hepatitis with features including antinuclear antigen positivity and histologic evidence of chronic active hepatitis that can lead to misdiagnosis and inappropriate treatment. Introduction of another class of NSAID in many of these patients appeared to be safe. In a retrospective study of 625 000 patients who received more than 2 million prescriptions for NSAIDs and who were evaluated for newly diagnosed acute liver injury, there were 23 cases of acute liver injury over the 4-year study period.³⁶

ALLERGIC AND CUTANEOUS REACTIONS

Various skin reactions may develop in association with the use of NSAIDs. Mostly these are morbilliform rashes and urticaria; severe, potentially life-threatening reactions such as toxic epidermal necrolysis and the Stevens–Johnson syndrome are uncommon.³⁷ These reactions are characterized by blistering skin lesions that may begin as erythematous macules and by target-like areas anywhere on the body. They may also lead to mucosal blistering or ulceration.

There has been concern that the sulfa-containing COX-2 inhibitors may cause hypersensitivity reactions in those with a known sulfa sensitivity.³⁸ Celecoxib and valdecoxib have a sulfonamide moiety whereas rofecoxib and etoricoxib have a methylsulfone side chain. Adverse reactions to sulfonamide antimicrobials include type I, or immunoglobulin E-mediated reactions, hypersensitivity syndrome reactions, and severe skin reactions, including toxic epidermal necrolysis and Stevens–Johnson syndrome. The aromatic amine portion of the sulfonamide antimicrobial is considered to be critical in the development of latter two reactions. In susceptible individuals, the hydroxylamine metabolite cannot be detoxified, leading to a cascade of cytotoxic and immunological events that eventually result in the adverse reaction. However, the major difference between sulfonamide antimicrobials and other sulfonamide-containing medications such as furosemide, thiazide diuretics, and celecoxib or valdecoxib, is that sulfonamide antimicrobials contain an aromatic amine group at the N4 position.

This allows for division of the sulfonamides into two groups: aromatic amines (i.e., sulfonamide antimicrobials) and nonaromatic amines. In addition, sulfonamide antimicrobials contain a substituted ring at the N1 position; this group is not found with nonaromatic amine-containing sulfonamides. Since celecoxib and valdecoxib do not contain the aromatic amine, adverse reactions such as hypersensitivity syndrome reactions and toxic epidermal necrolysis would not be expected to occur at the same frequency as they do with sulfonamide antimicrobials. Similarly, for IgE-mediated reactions, the N1 substituent and not the sulfonamide

THERAPEUTIC PRINCIPLES

There is no difference in efficacy between any nonsteroidal anti-inflammatory drug (NSAID) or cyclooxygenase-2 (COX-2) inhibitor when used in maximum doses

NSAIDs and COX-2 inhibitors should be prescribed as a therapeutic trial

They do not have disease-modifying effect and should only be continued if there is significant symptomatic benefit

The lowest effective dose should be used for the shortest time

NSAIDs should be avoided in the elderly and in those who are anti-coagulated, have significant concomitant disease, or with a history of previous gastrointestinal toxicity

Both NSAIDs and COX-2 inhibitors should be avoided in those with significant renal or cardiac disease and in very elderly and frail patients

moiety is important in determining specificity to antibodies. However, postmarketing surveillance studies found that reporting rates for Stevens–Johnson syndrome/toxic epidermal necrolysis with the sulfonamide coxibs were substantially higher than the background rate of 1.9 cases per million population per year, with the valdecoxib rate being 8–9 times that of celecoxib and approximately 25 times that of the background rate.

In the first 2 years of marketing, the reporting rate with valdecoxib was 49 cases per million person-years of use, 6 cases per million person-years for celecoxib and 3 cases per million person-years for rofecoxib.³⁹ On the basis of these data, the manufacturer withdrew valdecoxib from the market.

RESPIRATORY

The NSAIDs rarely induce pulmonary problems, although the actual incidence of adverse events is unknown. The principal pulmonary reactions that can occur include bronchospasm (which can be quite severe) and pulmonary infiltrates with eosinophilia. Precipitation or exacerbation of airway obstruction may occur in aspirin-sensitive individuals.⁴⁰ The syndrome of pulmonary infiltrates with eosinophilia can occur in patients receiving NSAIDs. It is not known whether this syndrome is associated with specific NSAIDs, or a general class effect. In one review, the typical presentation consisted of fever, cough, dyspnea, infiltrates on chest X-ray, and an absolute peripheral eosinophilia. Pathological examination revealed poorly defined granulomas with infiltrating eosinophils. Glucocorticoids were required, along with discontinuation of the drug, in order to reverse the process.

CENTRAL NERVOUS SYSTEM

The reported central nervous system side effects of NSAIDs include aseptic meningitis, psychosis, and cognitive dysfunction.⁴¹ Psychosis and cognitive impairment are more prevalent in elderly patients, particularly those taking indometacin. Aseptic meningitis seems to be more prevalent in patients with systemic lupus erythematosus who are treated with NSAIDs of the phenylpropionic acid class, such as naproxen or ibuprofen, but the diagnosis should be considered in any patient with aseptic meningitis who has been using NSAIDs.

Tinnitus is a common problem, particularly in patients prescribed high doses of salicylates, although it can occur with all the NSAIDs. Tinnitus is typically reversible upon cessation of drug therapy, and should be regarded as a warning sign that patients are developing high blood levels of the drug. However, this may not be as evident in patients at the extremes of age.

PREGNANCY AND LACTATION

Aspirin has a role in prevention of pre-eclampsia and the treatment of the anti-phospholipid syndrome (Chapter 61), and it is not associated with an increased risk of miscarriage when used later in pregnancy. However, the inhibition of prostaglandin synthesis by NSAIDs, particularly by aspirin, can result in premature closure of the ductus arteriosus, and other effects have been suggested, including smaller babies and neonatal bruising. However, the safety of these drugs has not been fully evaluated in pregnant women. If possible, NSAIDs and aspirin should be avoided by women who are trying to conceive and in early pregnancy but may be used during pregnancy in women who have significant rheumatic symptoms unrelieved with other treatment. The drugs should be stopped in the last 2 months of pregnancy to avoid potential bleeding complications and premature closure of the ductus arteriosus.

Antihistamines

Phil Lieberman, Vivian Hernandez-Trujillo,
Jay Lieberman, Anthony J. Frew

89

Histamine is found widely distributed through the body, with highest concentrations in lung, skin, and gastrointestinal tract. The majority is found in mast cells and basophils. Histamine also exists in the central nervous system, epidermal cells, gastric mucosa, and rapidly growing tissue.

HISTAMINE RECEPTORS

The actions of histamine are mediated by at least four receptor types (H_1 , H_2 , H_3 , H_4). All of these are G protein-coupled receptors.¹ The activities of histamine are summarized in Table 89.1.

In general H_1 receptors exert activity by producing changes in free cytosolic calcium, and H_2 receptors mediate responses by producing elevations in cyclic adenosine monophosphate (cAMP). H_3 and H_4 receptors utilize both mechanisms and can also decrease cyclic AMP.¹

The histamine-binding site on the H_1 receptor consists of five amino acids. H_1 receptors are probably the most important in relation to the production of symptoms of immediate hypersensitivity reactions. The major effects produced by stimulation of H_1 receptors include bronchial smooth-muscle contraction that can cause wheezing, stimulation of peripheral nerve endings causing pruritus, stimulation of the vagus inducing reflex bronchoconstriction and cough, and an increase in vascular permeability with peripheral vasodilatation resulting in a fall in blood pressure.²

The H_2 receptor is a member of the heptahelical receptor family. It is linked to a G protein that activates adenyl cyclase and thus increases cAMP formation. This increase in cAMP produces a rise in intracellular calcium that mediates calcium-calmodulin actions in the gastric mucosa, vascular smooth muscle, brain, adipocytes, basophils, neutrophils, and other tissues.

The H_3 receptor has been found principally in the central nervous system. H_3 receptors are located in the hippocampus, the thalamus, the amygdala, and the hypothalamus. Most H_3 receptors are on presynaptic sites on histaminergic nerve terminals. They tend to be “inhibitory receptors.” H_3 receptors are also found on peripheral nerve afferent neurons and reduce nerve repolarization when stimulated. H_3 receptors have also been detected in vascular beds.

H_4 receptors are found principally on peripheral blood cells. Their distribution suggests that they might be active in regulation of immune responses. They are also located in the bone marrow, colon, small intestine, and lung.

ACTIVITY OF HISTAMINE ON TARGET ORGANS

VASCULAR BED

The overall effect of histamine on the vascular bed is dilatation, which results in flushing, lowering of peripheral resistance, and a fall in systolic blood pressure.² In addition there is an increase in capillary permeability, mainly caused by a separation of the endothelial cells of the postcapillary venules, exposing the permeable basement membrane. Vasodilatation is mediated by both H_1 and H_2 receptors, with maximal vasodilatation achieved when both are stimulated. H_1 receptors have higher affinity for histamine, are stimulated by a lower concentration of histamine, and mediate a rapid-onset and short-lived vasodilatation. The vasodilatation produced by H_2 receptors is slower in onset but longer-lasting. Therefore, H_1 antagonists are more effective in blunting vasodilator responses at low concentrations of histamine and less effective at higher concentrations, which activate the H_2 receptor.²

H_2 receptors exert their effect via a direct action on the vascular smooth muscle, whereas H_1 receptors exert their effect not only directly on smooth muscle but also indirectly by stimulation of endothelial cells. Endothelial cell stimulation results in the production of nitric oxide and possibly prostaglandin I_2 (PGI_2). This indirect vasodilatory action plays an important role in the cumulative vasodilatory response mediated by H_1 receptors and is a function solely of the H_1 receptor.

H_3 receptors also play a role in vascular responses, as evidenced by animal models of anaphylaxis³ and nasal challenge studies involving the application of histamine to the human nasal airway.⁴ H_3 -receptor stimulation of presynaptic terminals of sympathetic effector nerves innervating the heart and systemic vasculature as well as the nasal vasculature inhibits its endogenous norepinephrine release. Since norepinephrine is involved

Table 89.1 Histamine and its activities

Receptor	H ₁	H ₂	H ₃	H ₄
Signal conduction through	G _{q/11} and others	G _s	G _{i/o}	G _{i/o} and G _{15/16}
Location of receptors	Multiple sites throughout the body, including: smooth-muscle bronchi and gastrointestinal tract, cardiac tissue, blood vessels, sensory nerves, endothelium, central nervous system	Widely expressed, including: mucosa of stomach, cardiac tissue, uterus, smooth-muscle vascular bed, epithelium of mucosa of nose, submucosal glands in nose, central nervous system, immune cells	Mainly expressed on presynaptic nerves in the peripheral sympathetic adrenergic system and histaminergic nerves in the central nervous system. Receptors can be found in airways and gastrointestinal tract	Eosinophils, neutrophils, basophils, mast cells, spleen, liver, lung, colon, epicanthus, and bone marrow
Chromosome location	3p25, 3p14-21	5q35.3	20q13.33	18q11.2
Signal conduction induces	Increased cyclic guanosine monophosphate, increased intracellular cytosolic calcium, activation of phospholipase C, activation of guanyl cyclase, nitric oxide production	Increase in cyclic adenosine monophosphate (AMP), activation adenyl cyclase	Decreased cyclic AMP, induction of mitogen-activated protein (MAP) kinase	Decreased cyclic AMP, MAP kinase induction, phospholipase C activation, formation of diacylglycerol, calcium mobilization
Antagonists (reverse agonists)	Over 40 exist. Examples of 'second generation' include cetirizine, desloratadine, fexofenadine, loratadine, azelastine	Burimamide, cimetidine, dimaprit, famotidine, nizatidine, ranitidine, and others	None available clinically: thioperamide, alobenpropit, and others	None available clinically: has homology with H ₃ receptor and is also antagonized by same drugs
Activities	Increases vascular permeability, producing a fall in blood pressure, flush, headache, and reflex tachycardia; itch; smooth-muscle contraction in bronchi and gastrointestinal tract; stimulation of vagal nerve receptors producing reflex smooth-muscle contraction in airways; cough via stimulation of sensory nerves in airways; eosinophil chemotaxis; decreased atrioventricular node conduction time; enhancement of release of histamine and arachidonic acid derivatives; nitric oxide formation	Increased gastric acid secretion; increases vascular permeability, producing a fall in blood pressure, flush, headache, and reflex tachycardia; stimulate mucus production in the lungs; direct chronotropic effect on atrium and inotropic action on ventricle; relaxation of esophageal sphincter; stimulation of suppressor T cells; decrease neutrophil and basophil chemotaxis and activation; proliferation of lymphocytes; activity of natural killer cells	Opposes bronchoconstriction and gastric acid; suppression of norepinephrine release at presynaptic nerve endings	Chemotaxis and chemokinesis of mast cells and eosinophils; enhancement of the activity of other chemoattractants (e.g., chemokines) on eosinophils; upregulation of adhesion molecules

in correction of hypotension in shock and in the homeostasis of normal airway patency, such stimulation can prevent compensatory sympathetic response to shock and result in increased nasal airway resistance due to intranasal vascular dilatation. Thus, H₃-receptor blockade in animal models of allergic shock improves cardiovascular responses,³ and H₃

antagonists will reverse the intranasal congestion occurring as a result of histamine-induced nasal blockage.⁴

It stands to reason, therefore, that antagonism of all three receptors (H₁, H₂, and H₃) would be beneficial in the context of shock due to anaphylaxis as well as congestion occurring during rhinitis. It has been

demonstrated that a combination of H₁ and H₂ antagonism is more effective than either alone in correcting symptoms of flush, headache, and blood pressure changes occurring during intravenous infusion of histamine in human volunteers.²

HEART

The effect of histamine on the heart is mainly mediated through the H₂ receptor. However the H₁ receptor also plays a significant role. The vasodilatory response to histamine results in a reflex tachycardia. In addition histamine exerts a direct effect on the heart that is both chronotropic and inotropic. H₂-receptor stimulation increases the rate and force of both atrial and ventricular contraction, probably by enhancing calcium influx. H₁-receptor activation speeds the heart rate by hastening diastolic depolarization of the sinoatrial node. Contraction of the coronary arteries is mediated through the activity of the H₁ receptor.

EXTRAVASCULAR SMOOTH MUSCLE

Histamine produces varying effects on extravascular smooth muscle, including smooth-muscle contraction in the bronchial tree, mediated via the H₁ receptor. The H₁ receptor also produces modest contraction of the smooth muscle of the human uterus, whereas the H₂ receptor can produce uterine relaxation. The gastrointestinal smooth-muscle response varies from species to species, but the predominant effect is contraction, which is mediated through the H₁ receptor.

GLANDULAR SECRETION

An important biologic effect of histamine in hypersensitivity reactions is the excess production of mucus, which appears to be mediated through both H₁ and H₂ receptors. The H₂ receptor increases the amount of mucus glycoprotein secretion from goblet cells and bronchial glands, whereas the H₁ receptor increases the viscosity of the mucus.

IMMUNE REGULATION

Histamine regulation of immune and inflammatory responses is mediated through the H₂ receptor and appears to be directly related to an increase in intracellular cAMP. This results in a negative feedback on basophil (but not mast cell) histamine release. It also produces several effects on lymphocytes *in vitro*, including inhibition of T-cell-mediated cytotoxicity, activation of suppressor T cells, decrease in immunoglobulin production, and suppression of lymphocyte proliferation and lymphokine production. In addition, H₂-receptor stimulation can decrease monocyte secretion of complement components, inhibit neutrophil superoxide production, and modulate neutrophil chemotaxis.

It is reasonable to assume that, since H₄ receptors are found on leukocytes, including eosinophils, histamine might play a role in the immunologic inflammatory response. Stimulation of eosinophils by histamine can induce chemokinesis as well as chemotaxis. Those activities are inhibited by an H₄ antagonist. H₄ antagonists also reduce histamine-induced upregulation of adhesion molecules. H₄ stimulation can also cause chemotaxis of mast cells and thus it can be postulated that the H₄ receptor is active in recruiting mast cells to areas of

KEY CONCEPTS

- >> Histamine exerts its activities via four well-characterized G protein-coupled receptors
- Major effects via H₁ receptor
 - >> Smooth-muscle contraction
 - >> Pruritus
 - >> Vascular dilatation and permeability
- Major effects via H₂ receptor
 - >> Gastric acid secretion
 - >> Inotropic and chronotropic cardiac stimulation
- Major effect via H₃ receptor
 - >> Reduced postsynaptic release of norepinephrine
- Major effect via H₄ receptor
 - Downregulation of activity of eosinophils, basophils, T cells
 - Antagonism of the activity of histamine at H₁, H₂, and H₃ receptors could be of benefit in the management of allergic disease.

KEY CONCEPTS

ANTI-ALLERGIC, ANTI-INFLAMMATORY ACTIVITIES OF SECOND-GENERATION ANTIHISTAMINES

- >> Prevent mast-cell degranulation
- >> Downregulate expression of adhesion molecules
- >> Diminished chemotaxis of eosinophils
- >> Reduction in inflammatory cytokine expression
- >> Enhanced programmed cell death of eosinophils

allergen challenge, thereby amplifying histamine-mediated allergic reactions.

ANTI-ALLERGIC, ANTI-INFLAMMATORY EFFECTS OF ANTIHISTAMINES

Over the last 20 years, there has been increasing interest in the potentially beneficial effects of second-generation antihistamines that are unrelated to their antihistaminic activity. This 'anti-allergic-anti-inflammatory' activity has been demonstrated in numerous spheres with most second-generation antihistamines, in studies mainly targeted at examining the drugs' roles in prevention of mast cell and basophil degranulation, downregulation of adhesion molecules, regulation of eosinophil chemotaxis and apoptosis, and modulation of cytokine production.

EFFECT ON MAST CELL AND BASOPHIL DEGRANULATION

Perhaps the most-researched anti-inflammatory activity of antihistamines relates to their ability to inhibit mediator release from mast cells and basophils. This effect has been demonstrated both *in vitro* and *in vivo*.⁵ Suppression of mast cell and basophil degranulation, as measured by either release of preformed proinflammatory mediators (e.g., histamine) and/or newly synthesized molecules (e.g., arachidonic acid metabolites) has been demonstrated for both immunologic and nonimmunologic stimuli including allergen, anti-IgE, *N*-formyl-methionyl-leucyl-phenylalanine (fMLP), compound 48/80, substance P, concanavalin A, and calcium ionophore A23187.

In general, all second-generation antihistamines show inhibition of inflammatory mediator release from mast cells and basophils *in vitro*, but there is a great degree of heterogeneity between drugs depending on the different stimuli and different experimental conditions. In addition, at higher doses these drugs can induce release (see below). For example, when Okayama et al.⁶ studied the effects of terfenadine, ketotifen, and cetirizine on human lung, tonsil, and skin mast cells stimulated immunologically with anti-immunoglobulin E (IgE), they found varying results both between drugs and within the same drug. Terfenadine inhibited mediator release from all tissue mast cells in the 5–10 μ M range, while it enhanced release above 10 μ M from the lung and skin mast cells, but not from the tonsillar mast cells. Ketotifen, on the other hand, was a weak inhibitor of histamine release, and only induced release from skin mast cells, whereas cetirizine caused inhibition of both histamine and PGD₂ release from all tissues, yet did not induce release from any tissue at higher concentrations.⁶ The absence of a comprehensive comparison makes interpretation of the observed differences difficult, but nonetheless most evidence supports the idea of inhibition of mediator release from mast cells and basophils by antihistamines *in vitro*.

In addition to the heterogeneity observed from *in vitro* studies, the clinical studies looking at the effect of antihistamines on release of inflammatory mediators have also been varied. Most of these studies have measured inflammatory mediators in the nose or skin, and have found evidence, once again, to be supportive of the anti-inflammatory role of these drugs. However, there is still inconclusive evidence for a definitive effect *in vivo*.

EFFECTS ON EXPRESSION OF ADHESION MOLECULES

Downregulation of expression of cellular adhesion molecules, specifically intracellular adhesion molecule (ICAM-1), has been shown for levocabastine, fexofenadine, terfenadine, and desloratadine *in vitro*.⁷

Even more persuasive are the clinical trial data over the last decade demonstrating the effects of various antihistamines on ICAM-1 expression and inflammatory infiltration in the nose and eyes. Azelastine, levocabastine, cetirizine, oxatamide, terfenadine, fexofenadine, mizolastine, and loratadine decrease ICAM-1 expression on either nasal and/or conjunctival epithelial cells and reduce inflammatory infiltrate in mucosal tissues *in vivo*, effects observed both after allergen challenge and during natural antigen exposure.⁷ In most studies, clinical symptom scores decreased concurrently with ICAM-1 expression.

EFFECTS ON CHEMOTAXIS AND APOPTOSIS

A third anti-inflammatory effect of antihistamines is their ability to regulate eosinophil and neutrophil chemotaxis and to increase eosinophil apoptosis. Fexofenadine, ketotifen, cetirizine, terfenadine, loratadine, and desloratadine decrease eosinophil chemotaxis *in vitro* while ketotifen, terfenadine, azelastine, and cetirizine decrease neutrophil chemotaxis *in vitro*.⁵ This inhibition of eosinophil accumulation may be mediated by downregulation of adhesion molecule expression or by a direct antichemotactic effect.⁸ In addition to hampering eosinophil migration, two antihistamines, ketotifen and cetirizine, also increase programmed cell death of eosinophils in the presence of interleukin-5 (IL-5).

EFFECTS ON CYTOKINE EXPRESSION

In vitro, desloratadine inhibits IL-4 and IL-13 release from anti-IgE-stimulated human monocyte cytokine patterns *in vivo* by diminishing production of TH2-related cytokines and IL-8.^{8,9}

MECHANISMS OF ACTION RELATIVE TO ANTI-ALLERGIC, ANTI-INFLAMMATORY ACTIVITIES

Effects on mast cell and basophil degranulation

The exact mechanism by which antihistamines prevent mast cell and basophil degranulation is unknown. It appears that these effects are not related to H₁-receptor binding affinity, and it is very unlikely that they result from H₁-receptor blockade.

Two hypotheses have been proposed to explain the effects of antihistamines on mast cell and basophil degranulation. Some work suggests that the polar nature of these drugs, which contain both lipophilic and cationic regions, is a factor in their ability to inhibit mast cell mediator release. It is thought that the lipophilic portion, by dissolving into the cell membrane, could, at low concentrations, physically stabilize the membrane and/or interact with proteins involved in signal transduction, decreasing downstream activity. Also, at higher concentrations, the insertion of the lipophilic portion of these drugs into the cell membrane could destabilize it, causing membrane disruption and release of the preformed inflammatory mediators.

The second hypothesis suggests that antihistamines could modify degranulation by modulating calcium flux, either by interfering with calcium channels, thereby competitively inhibiting the binding of calcium to the cell membrane, or by effecting intracellular calcium release.

Effects on expression of adhesion molecules and cytokines

The effects of antihistamines on ICAM and cytokine expression may be mediated by antihistamines regulating expression of proteins, by decreasing activity of transcription factor NF- κ B. This has been shown *in vitro* for desloratadine, pyrilamine, cetirizine, loratadine, and fexofenadine. In contrast to the mechanisms proposed to explain inhibition of mast cell degranulation, this downregulation of protein synthesis appears to be directly related to the H₁ receptor, as antihistamines had no effect on NF- κ B activity in the absence of the H₁ receptor.^{9,10}

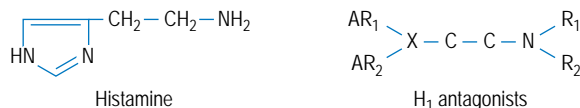

Fig. 89.1 Structure of histamine and the basic formula of classic H_1 antagonist.

CLASSIC, FIRST-GENERATION H_1 ANTAGONISTS

Structure–function relationships and chemical classification

Although it is clear that classification schemes dependent on chemical structure are imperfect, such classification still has merit since it provides insight into mechanisms of action. This traditional classification scheme is outlined in Figures 89.1 and 89.2 and Table 89.2.

Most, but not all, first-generation H_1 antagonists have a structural resemblance to histamine in that they contain a substituted ethylamine moiety. With the development of newer agents that do not have an ethylamine moiety, it has become evident that antihistaminic activity does not require this shared structure. It is now known that most, if not all, available antihistamines are not competitive antagonists, but inverse agonists.¹⁰ This concept is based on the state in which a histamine receptor exists. At equilibrium, the histamine receptor exists in both active and inactive states. Whereas agonists such as histamine preferentially bind the active state, inverse agonists such as antihistamines bind the inactive state. Therefore, when antihistamines bind the histamine receptor, this results in the receptors being held in the inactive state, in which histamine is unable to exert its effects (Fig. 89.3).

The prototype basic structure of the ethylamine-containing first-generation H_1 antagonists (which represent the majority of drugs) is compared to histamine in Figure 89.1. These drugs contain the ethylamine moiety attached to aromatic substituents (AR_1 , AR_2) by a nitrogen, carbon, or oxygen linkage (X). The two aromatic rings may be bridged, as in tricyclic antihistamines, or the ethylamine may actually be part of a ring structure. The classification of first-generation H_1 antagonists has traditionally been based on the atom linking the ethylamine grouping to the aromatic substituents (Fig. 89.2). If the link is via oxygen, the drugs are ethanolamines; if via carbon, they are termed alkylamines; and if via nitrogen, they are ethylenediamines. This structural classification does not apply to piperazines, piperidines, and phenothiazines. The aromatic substituents in these compounds make them lipid soluble, so they pass through the blood–brain barrier.

Pharmacokinetics

All first-generation H_1 receptor antagonists are rapidly absorbed after oral administration and reach peak serum concentrations in 2–3 hours when given in liquid form. Most have a duration of action of 4–6 hours, but some have longer durations of action. Studies of diphenhydramine suggest that H_1 antagonists are disseminated throughout the body, including the central nervous system. Antihistamines are secreted in breast milk, and the concentration is dependent upon serum concentration.

Fig. 89.2 Structural classification of classic H_1 antagonists.

Table 89.2 Characteristics of representative first-generation H₁ antagonists based upon chemical classification

Chemical class	Examples	Comments
Ethanolamines	Diphenhydramine Clemastine Carbinoxamine	Significant antimuscarinic effects. Can be potent sedatives, but sedative potential varies, with clemastine producing the least amount. Low incidence of gastrointestinal side effects. Can have some anti-motion sickness activity. Diphenhydramine and clemastine both available over the counter
Alkylamines	Chlorpheniramine Brompheniramine Dexchlorpheniramine Triprolidine	Relatively moderate incidence of drowsiness. Moderate anticholinergic effect. No anti-emetic or anti-motion sickness activity. Few gastrointestinal side effects. All available over the counter. Occasional paradoxical central nervous system stimulation, especially in children
Ethylenediamines	Tripelennamine Pyramine Antazoline	Mild to moderate sedation. Slight anticholinergic effect. Some local anesthetic effect. Pyramine is sold over the counter and is the oldest antihistamine preparation available today. As a group, may have more frequent gastrointestinal side effects
Piperazines	Hydroxyzine Meclizine Cyclizine	Hydroxyzine has highest sedative activity in group. Meclizine and cyclizine relatively low sedative activity, with main use being for vertigo, anti-motion sickness, and anti-emetic activity. Hydroxyzine has significant anticholinergic activity
Piperidines	Cyproheptadine Phenindamine Azatadine	Mild to moderate sedation. Little anticholinergic activity, anti-emetic activity, and anti-motion sickness activity. Cyproheptadine has potent anti-serotonin effect. As a class has relatively high incidence of paradoxical central nervous system stimulatory activity
Phenothiazines	Promethazine Methdilazine Trimeprazine	Usually highly sedating. Strong anti-emetic, anticholinergic activity. Main clinical use is as anti-emetic

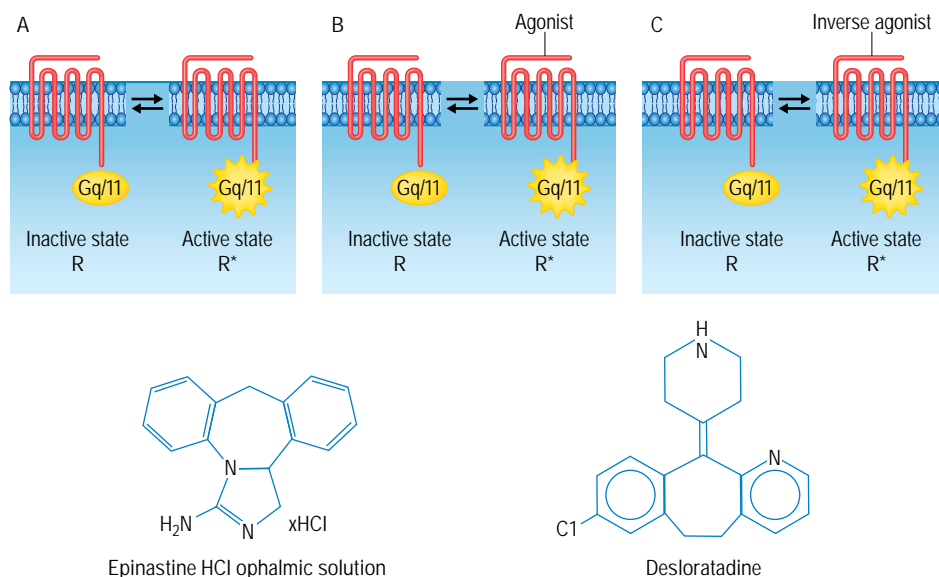

Fig. 89.3 The conformational states of the H₁ receptor. (A) Equilibrium exists at rest between active and inactive states. (B) Agonists (such as histamine) bind the active state preferentially, thereby shifting the equilibrium towards the active state. (C) Inverse agonists (such as antihistamines) bind the inactive state preferentially, thereby shifting the equilibrium towards the inactive state. (From Simons FER. Antihistamines. In: Adkins NF, et al. (eds) Allergy Principles and Practice, 6th edn, vol. 1. Philadelphia: Mosby; 2003:834–869 with permission.)

CLINICAL PEARLS**SIDE EFFECTS OF FIRST-GENERATION H₁ ANTAGONISTS**

- >> Drowsiness
- >> Central nervous system impairment that may occur without subjective drowsiness
- >> Potentiation of effects of alcohol, tranquilizers
- >> Impaired motor skills – driving, flying
- >> Paradoxical hyperactivity in some children
- >> Dryness of mouth
- >> Urinary retention, constipation

All first-generation H₁ antagonists are extensively metabolized in the liver, and little, if any, of these drugs is excreted unchanged in the urine. All of these agents are metabolized by the hepatic cytochrome P450 system. Clearance rates are variable and half-lives differ according to the metabolic potential of the patient, such that children have shorter and the elderly have longer elimination half-lives. Severe hepatic dysfunction can prolong the half-life, and dosage regimens must be altered accordingly.

Pharmacodynamics

An important principle of the pharmacodynamic activity of these drugs is that their tissue effect is somewhat delayed compared to serum levels and can extend far beyond the life of the drug in the serum.¹¹ For example, a single dose of hydroxyzine significantly suppresses histamine-induced wheal and flare for 36 hours, reducing the mean flare size for as long as 60 hours despite a negligible serum concentration. Also, the maximal suppression of wheal and flare does not occur until 7 hours after mean peak serum concentrations have been reached.¹¹ Thus it is best to administer H₁ antagonists before allergen exposure.

Side effects

By far the most common and significant side effect of first-generation antihistamines is drowsiness. Their soporific activity can clearly be attributed to the fact that these drugs pass through the blood–brain barrier and exert their effect on the central nervous system. The exact mechanism(s) by which these drugs produce drowsiness is unknown but may include antihistaminic, anti-cholinergic, anti- α -adrenergic, anti-serotonergic, and/or calcium channel blocking activities. It should be noted that antihistaminic activity does not necessarily correlate with sedative potential, suggesting that this is not the sole mechanism producing this side effect.

It is crucial to appreciate that the subjective degree of drowsiness does not necessarily correlate with the objective assessment of central nervous system impairment.¹² Since these drugs can produce impairment without apparent sedation and inhibit performance on tests of psychomotor reflexes and driving skills, civilian and military aircraft pilots are prohibited from taking these drugs while flying.

Paradoxical central nervous system stimulation can be encountered in some patients, especially children. Other less common central nervous system side effects include dizziness, tinnitus, blurred vision, and tremor.

CLINICAL PEARLS**KEY CLINICAL FEATURES OF SECOND-GENERATION ANTIHISTAMINES**

- >> Fexofenadine and desloratadine are nonsedating
- >> Loratadine is nonsedating in recommended doses, but may sedate in higher doses
- >> Cetirizine and azelastine can produce sedation, but are probably less sedating than first-generation drugs
- >> Cetirizine and loratadine are US Food and Drug Administration class B drugs in pregnancy

The next most frequent group of side effects is due to the anti-muscarinic activity and includes dryness of the mouth, urinary retention and dysuria, blurring of vision, and constipation.

Other side effects are uncommon and include loss of appetite, nausea, abdominal pain, and diarrhea. Drug allergy to antihistamines has been reported. Leukopenia, agranulocytosis, and hemolytic anemia are extremely rare. Although teratogenic effects have been noted in animals, these have not been documented in humans.

Acute toxicity resulting from overdose can produce central nervous system effects, including hallucinations, central nervous system excitement, profound sedation, ataxia, incoordination, and convulsions. Other findings are fixed and dilated pupils, as well as sinus tachycardia, which is frequent, and ventricular arrhythmias, which are less common. The anti-cholinergic effects of dry mouth and urinary retention are usually observed and fever may be present. Fatal overdose reactions have occurred, with profound coma and respiratory collapse.

NONSEDATING, SECOND-GENERATION ANTIHISTAMINES

A variety of second-generation antihistamines are available in different countries. Loratadine, desloratadine, cetirizine, and fexofenadine are administered orally, azelastine is administered orally or by nasal spray, while others (levocabastine, olopatadine, ketotifen, and epinastine) are available for ocular administration.

These drugs are not as easily classified by structure as are the first-generation antihistamines because they do not always contain an ethylamine side chain. Nonsedating antihistamines are of diverse chemical structure, and many can be considered drugs with multiple pharmacologic effects in addition to their antihistaminic activity. The term “non sedating” is actually somewhat of a misnomer since some of these drugs (cetirizine and azelastine) are mildly sedating at standard dosage, and others can be sedating when given in amounts exceeding the recommended dose.

Numerous studies have demonstrated that all second-generation drugs cause less in the way of significant subjective sedation or objectively assessed impairment of function.¹³ Many factors may account for the reduced sedative potential of these agents, but the most important seems to be that they do not pass through the blood–brain barrier.

Another postulated mechanism for their lack of sedation is their relative specificity for the H₁ receptor. In general, compared to first-generation antihistamines, they are highly specific for the H₁ receptor

and show little or no binding to muscarinic, 5-hydroxytryptaminergic, and α -adrenergic receptors. In addition, they appear to have a greater affinity for peripheral rather than central H_1 receptors.¹³

Pharmacokinetics for second-generation antihistamines

There are certain nuances that distinguish the pharmacokinetic profiles of these drugs. However, some generalizations can be made about their pharmacokinetics. From one perspective the second-generation antihistamines can be viewed as having similar, ring-structure, core moieties (Fig. 89.4) and therefore it appears to be the side chains joining the cores that may determine their absorption, elimination, and distribution.¹⁴ The distinctive pharmacokinetic profiles are summarized in Table 89.3.

All second-generation H_1 antagonists are well absorbed, and peak plasma concentrations are reached within a few hours after administration. They all appear to be well distributed into body tissues. Most are highly protein-bound in both circulation and tissue. Terminal elimination half-lives range from approximately 7 to 22 hours.

Loratadine and azelastine undergo extensive first-pass metabolism by the cytochrome P450 system in the liver. Shortly after single doses of these drugs the concentration of the metabolites is greater than that of the parent drug. In both instances the metabolites have antihistamine activity. On the other hand, neither cetirizine nor fexofenadine undergoes extensive liver metabolism, neither has active metabolites, and they are mostly excreted unchanged in the feces and urine. The P450 isoforms responsible for the metabolism of loratadine (CYP3A4 and CYP2D6) and desloratadine (CYP3A4) are known, whereas the isoform responsible for the metabolism of azelastine has not been established.

Of interest regarding the pharmacokinetics of antihistamines is the multidrug resistance transporter system, P-glycoprotein, which is responsible for active transport of medications, thereby limiting their absorption from the gastrointestinal tract and entrance into the central nervous system. In the intestine, the system transports molecules from the cell into the lumen, and in the central nervous system it prevents drugs from entering the central nervous system. P-glycoprotein regulation of drug plasma levels appears to be linked to the CYP3A4-P450 isoform. It appears to be responsible for transport of drugs that are metabolized by this P450 isoform; these include erythromycin, ketoconazole, quinidine, and verapamil. Thus far this system has not been shown to exert clinically important effects on the metabolism of second-generation antihistamines, but it appears to be responsible for the increase in plasma levels of fexofenadine when this drug is administered in conjunction with ketoconazole or erythromycin. Erythromycin increases the bioavailability of fexofenadine by 103% and ketoconazole increases it by 159%. Both erythromycin and ketoconazole appear to interfere with the external transport of fexofenadine via the P-glycoprotein system of the gut.¹⁵

Pharmacodynamics

The pharmacodynamic principles for second-generation antihistamines are similar to those for first-generation drugs. The pharmacodynamic profiles of selected second-generation antihistamines are shown in Table 89.4. Tissue activity is slightly delayed compared to serum levels, but, as a rule, tissue concentrations reach maximum level rapidly after oral administration, with cutaneous wheal-and-flare suppression occurring within 2 hours.¹⁶ In addition, activity in tissue may extend beyond the

Fig. 89.4 Structures of selected second-generation antihistamines.

presence of detectable blood levels.¹⁴ Peak tissue activity usually occurs 5–8 hours after oral administration of a single dose. The maximum activity can last for several hours, even when plasma concentrations have declined significantly. This indicates either the presence of active metabolites in the tissue, or perhaps high tissue-binding affinity and/or avidity. This accounts for an important clinical phenomenon, the persistence of tissue activity after the discontinuation of the drug (Table 89.5). This is of note for allergy evaluation by cutaneous testing. In most instances there is some suppression of wheal and flare for at least 24 hours after the drug is discontinued. Of the agents considered in this chapter, loratadine seems to account for the longest duration of suppression (7 days).¹⁴

Using histamine-induced wheal-and-flare suppression as a model, there appears to be no tachyphylaxis or tolerance resulting from the long-term administration of second-generation H_1 antagonists.¹⁷

LORATADINE

Loratadine is a derivative of azatadine. Its structure resembles that of the tricyclic antidepressants. It is more polar and less basic than the parent compound because of the addition of a carboxymethyl ester moiety. This modification decreases the central nervous system penetration of the drug. Loratadine does not contain an ethylamine grouping and therefore has no structural resemblance to histamine. Loratadine is relatively specific for the H_1 receptor; however, at higher doses there may be some anti-muscarinic, anti- α -adrenergic, anti-serotenergic, and anti-leukotriene activity. It is extensively metabolized by first-pass mechanism in the liver, generating descarbethoxyloratadine, an active antihistamine that is four times more potent than loratadine itself. Peak serum concentrations of loratadine occur 1–2 hours after dosing, and peak serum concentrations of descarbethoxyloratadine appear 1.5–3.5 hours after dosing. The elimination half-life of loratadine is 8–14 hours and that of its metabolite is 17–24 hours, which accounts for the 24-hour duration of action of the drug. Wheal inhibition is detected at 1.5 hours after administration, reaches a peak at 4–6 hours, and may last 36–48 hours. There is an approximate 50% diminution in wheal and flare after a single 10-mg dose.

With regard to drug interactions, amiodarone taken with loratadine can result in torsade de pointes. Nefazodone should not be taken with loratadine since QT prolongation has been observed.¹⁸

DESLORATADINE

Desloratadine is a metabolite of loratadine. The onset of action is within 1 hour. Peak serum concentrations of desloratadine appear 3 hours after dosing. The mean elimination half-life of desloratadine is 27 hours and that of its metabolite is 36 hours. The consumption of food does not interfere with absorption of desloratadine. Wheal inhibition is detected 1 hour after administration and may last 24 hours.

Desloratadine has several effects, including decreased proinflammatory cytokine release, as well as inhibition of T-cell allergic responses and bronchial hyperresponsiveness, as shown in murine models of asthma.¹⁹ In humans, desloratadine has been shown to decrease the use of rescue medication and improve spirometric parameters in asthmatics with seasonal allergic rhinitis.²⁰ Desloratadine has also been shown to decrease nasal congestion in patients with allergic rhinitis and decreases reactions associated with cold-induced urticaria.¹⁸

CETIRIZINE

Cetirizine is a carboxylic acid metabolite of hydroxyzine with the carboxyl group having a negative charge at physiologic pH. Cetirizine is highly specific for the H_1 receptor, demonstrating no anti-cholinergic, anti-serotenergic, or calcium channel blocking activity. Absorption from the gastrointestinal tract is rapid, with maximum serum concentrations 1 hour after oral administration of a 10-mg dose. Cetirizine has a mean plasma half-life of approximately 8 hours and its terminal elimination half-life is nearly 25 hours. Cetirizine is not significantly metabolized in the liver. Only 8–10% is metabolized by the P450 cytochrome oxidase pathway.

This may make it the drug of choice in patients who have liver disease or are taking other drugs affecting the cytochrome P450 enzyme system. The serum elimination half-life of cetirizine is less in children than in the elderly and is markedly prolonged (19 hours) in adults with renal insufficiency. Its time course in the plasma closely parallels its wheal inhibition activity, with maximum inhibition achieved between 4 and 8 hours. The mean percentage inhibition of the histamine-induced wheal reaction is approximately 73%, and some inhibition is still detectable at 36 hours.

Alcohol consumption while taking cetirizine results in sedation and driving impairment.

Cetirizine reduces both the early- and late-phase cutaneous reactions to allergen injection.²¹ This is thought to be due to modulation of the migration of inflammatory cells, especially eosinophils, to the site of the reaction.¹⁴ This anti-inflammatory activity may also account for its ability to diminish the lesions of delayed-pressure urticaria, whereas other antihistamines are normally ineffective in this condition.²² In addition, cetirizine has been used in the treatment of many allergic disorders, including acute urticaria/angioedema, several physical urticarias, atopic dermatitis, and nasal polyposis.¹⁸ Like desloratadine, cetirizine has also been shown to improve asthma symptoms in patients with rhinitis and asthma.¹⁸

FEXOFENADINE

Fexofenadine, at a dose of 60 mg b.i.d., reaches a mean plasma concentration 2.6 hours after the dose with a mean elimination half-life of 14.4 hours. Like cetirizine, it undergoes no significant hepatic biotransformation. Approximately 80% of the dose of the drug is recovered in unchanged form in the feces, and approximately 12% in the urine. The half-life of fexofenadine in healthy adults ranges from 11 to 15 hours. Renal disease results in somewhat slower elimination, although this is of no clinical significance unless impairment is marked. Hepatic impairment does not affect absorption or elimination to any significant extent. Both erythromycin and ketoconazole increase plasma levels of fexofenadine, while food decreases its bioavailability.

Fexofenadine causes peak suppression of histamine-induced wheal and flare between 3 and 12 hours after single-dose administration. There is still significant suppression at 24 hours. When given for a week, it has residual effects on histamine suppression for 2 days after cessation of administration.

Fexofenadine has been shown to decrease nasal congestion in patients with allergic rhinitis, as well as improving pruritus in adults with atopic dermatitis.¹⁸

AZELASTINE

Azelastine is unique among antihistamines presently available in the USA because it is administered by nasal spray. After intranasal administration, its systemic bioavailability is approximately 40%. Azelastine has an onset of action within the first hour of administration and reaches peak activity at 1–3 hours after administration. Duration of activity is about 12 hours. Intranasal administration results in maximal plasma concentrations in 2–3 hours. Azelastine has an active metabolite, desmethylazelastine, which probably extends the duration of action of the drug. The half-life of the parent compound is 22 hours and that of the active metabolite 54 hours. Ten days after oral administration of 4 mg radiolabeled azelastine, approximately 24% of the radioactivity was recovered in the urine and 75% in the feces.

Table 89.3 Single-dose pharmacokinetics of selected second-generation antihistamines in healthy adults

Drug	Major metabolite	Activity of metabolite	Dose (mg)	T_{\max} (h)
Loratadine	Descarboethoxy	4 × parent	10 q.d.	1.2 ± 0.3

Pending	Effective	Most studies indicate beneficial effect	–	–	–	–

Some suppression of histamine-induced skin wheal and flare has been seen after the intranasal administration of azelastine but this effect is probably of little clinical significance and disappears within 48 hours of cessation of the drug.

Azelastine is also somewhat unusual in terms of its clinical effects: it reduces nasal obstruction and decreases postnasal drip. It appears to be effective as monotherapy in chronic nonallergic rhinitis.^{23,24}

The incidence of sedation in clinical trials appears to be low (approximately 2–3%).²⁴

■ ANTIHISTAMINES AVAILABLE ONLY FOR OCULAR USE ■

Several antihistamines are available as topical preparations for the treatment of allergic conjunctivitis. These include ketotifen, levocabastine, olopatadine, and epinastine.

KETOTIFEN

Ketotifen, like azelastine, has potent nonantihistamine anti-inflammatory activity. It inhibits mediator release from mast cells and basophils, degranulation of eosinophils and neutrophils, chemotaxis of eosinophils, leukotriene generation, and the generation of platelet-activating factor.²⁵

After oral administration, ketotifen is completely absorbed, with peak concentrations occurring at about 3 hours. The absorption half-life is about 1 hour. The absorbed drug is distributed extensively to circulating cells and 16–18% is bound to plasma proteins. Some 69–70% of the dose is excreted as metabolites. Both ketotifen and its metabolites appear to be largely excreted in the urine, with fecal elimination found only after the first 24 hours. Based on the above pharmacokinetic data, it is assumed that any ketotifen that is systemically absorbed after ophthalmic application would be extensively metabolized and eliminated via the urine. The recommended dosage is one drop every 8–12 hours.

LEVOCABASTINE

Levocabastine absorption from the eye occurs within 1–2 hours. Bioavailability from topical ocular administration ranges from 30% to 60%. Steady-state plasma levels after the application of a 0.05% ophthalmic suspension one drop three times a day are 1.6 µg/l. The drug has a plasma protein binding of approximately 65%.

The half-life of levocabastine is fairly long: between 35 and 40 hours regardless of the route of administration. There is very little hepatic metabolism, with about 75% of the drug excreted unchanged in the urine and 10–20% unchanged in the feces. The recommended dosage is one drop in each eye b.i.d. to q.i.d. Eye drops administered regularly do not suppress histamine-induced skin wheal and flare.²⁶

OLOPATADINE

Olopatadine also appears to have significant anti-inflammatory activity, and inhibits histamine release from mast cells. It is a selective H₁ antagonist that is devoid of effects on α-adrenergic, dopaminergic, and muscarinic receptors. The recommended dose is 1–2 drops in each affected eye b.i.d. at an interval of 6–8 hours. Peak serum concentrations are usually reached within 2 hours of dosing. The half-life in plasma is approximately 3 hours and elimination is primarily through renal excretion, with 60–70% of the dose recovered in the urine as the parent drug. Two metabolites are found in low concentrations in the urine: the mono-desmethyl and *N*-oxide moieties.

EPINASTINE

Like ketotifen, olopatadine, and azelastine, epinastine inhibits histamine release from mast cells. Although it is selective for H₁ receptors, it has affinity for H₂, α-adrenergic, and serotonin receptors as well. The peak plasma concentrations are usually reached within 2 hours of dosing. The plasma protein binding of epinastine is 64%, with a terminal plasma elimination half-life of 12 hours. It is excreted unchanged for the most part, with less than 10% of the drug metabolized. Epinastine has 55% excretion in the urine and 30% fecal elimination. The recommended dosage is one drop b.i.d.

SIDE EFFECTS OF SECOND-GENERATION ANTIHISTAMINES

As a class, the second-generation antihistamines have relatively few side effects. Some sedation can occur with azelastine and cetirizine, but its incidence is lower than with first-generation antihistamines.

None of the presently available drugs is known to prolong the Q-T interval, on their own, and none of them therefore carries any warning regarding the production of ventricular arrhythmias.

There is no evidence to date that any of the second-generation antihistamines cause fetal abnormalities in humans. They do, however, cross the placenta. In high doses, loratadine and hydroxyzine cause embryotoxicity in animals, and despite the lack of hard evidence from human studies, regulators and manufacturers advise against using all second-generation antihistamines in pregnancy. It is likely that all second-generation antihistamines are excreted in breast milk,²⁷ but there is no evidence that they exert any clinically significant side

effects in nursing infants. However nursing mothers are warned against their use.

Although astemizole was associated with increase in body weight and appetite, none of the newer antihistamines has been known to affect appetite or weight gain, when administered in standard doses by approved routes of administration.

Immunomodulating pharmaceuticals

90

Edwin S.L. Chan, Stephen N. Oliver, Bruce N. Cronstein

Recent excitement over biologic agents and their ability to regulate immunologic reactions and significantly affect such immunologically mediated diseases as rheumatoid arthritis and Crohn's disease has overshadowed previous emphasis on small molecules for the treatment of immunological diseases. Nonetheless, some small molecules (most notably methotrexate) have proved to be nearly as effective as biological agents when tested head-to-head in patients with immunological diseases, and combining these small molecule therapies with biological agents generally leads to significantly better outcomes than the use of either single agent. Thus, it is likely that many small molecule immunomodulatory drugs will continue to be widely used for many years to come. The most well-accepted and commonly used immunomodulators in current clinical use are reviewed here.

METHOTREXATE

Now regarded as a landmark agent among immunomodulatory pharmaceuticals, the history of this drug dates back to the 1940s, when Farber et al.¹ first reported temporary remissions achieved in children with acute lymphocytic leukemia. The treatment, aminopterin, a derivative of folic acid, was later to find a new disguise whereby a methyl group substitution resulted in methotrexate (Fig. 90.1). Methotrexate has been employed in the treatment of rheumatoid arthritis (RA) since as early as 1951, but its popularity as an immunomodulatory drug in RA did not come until the 1980s. Over the years, extensive experience with its use in inflammatory diseases as diverse as RA, psoriasis and inflammatory bowel disease has taught us a great deal about its safety, efficacy, and toxicities, as well as its anti-inflammatory mechanisms of action. In this respect, methotrexate, much like corticosteroids, can be justly regarded as a cornerstone of immunomodulatory therapy.

PHARMACOKINETICS OF METHOTREXATE

When used as an anti-inflammatory agent, methotrexate is administered at low doses (usually 10–25 mg/week) once weekly, usually orally, but may also be given via the subcutaneous or intramuscular routes. At these

low doses oral bioavailability is high (60–70%), and although transporters are responsible for its absorption from the gastrointestinal tract, no saturation effect occurs with these low doses. A small proportion of methotrexate is metabolized by hydroxylation into 7-hydroxymethotrexate, and both of these compounds are short-lived with a serum half-life of no more than 8 hours. The much longer anti-inflammatory action, which allows for once-weekly dosing, must therefore be attributable to other, longer-lasting metabolites, the polyglutamates. Excretion occurs principally via the urinary tract, but also via the biliary tract. Therefore renal function is an important consideration in methotrexate dosing, and any medication that impairs glomerular filtration may also potentiate both the effect and the toxicity of methotrexate.¹

MECHANISMS OF ACTION

Methotrexate is an analog of folic acid, which inhibits purine and pyrimidine synthesis and thereby suppresses the cellular proliferation important for the growth of malignant tumors (Table 90.1). These actions are highly dependent on its ability to inhibit dihydrofolate reductase, and hence the toxicity arising from high-dose methotrexate therapy can similarly be treated with folic acid derivatives, such as leucovorin, which is used as an antidote for methotrexate given as a chemotherapeutic agent. However, it may come as a surprise that folic or folinic acid is often given in conjunction with methotrexate in inflammatory diseases to reduce the incidence of side effects such as mucositis and bone marrow suppression, without hampering its anti-inflammatory efficacy. Reductions in the levels of purines and pyrimidines in the serum have indeed been observed following a single dose of methotrexate, along with decreased proliferation of antigen stimulated lymphocytes. However, these changes are transient and insufficient to explain the anti-inflammatory effectiveness of once-weekly dosing. This, and the fact that methotrexate is anti-inflammatory at only one-thousandth of the anti-malignant dose, must mean that the anti-inflammatory actions are mediated mostly through different mechanisms from those responsible for suppression of tumor growth.

Methotrexate is also known to block transmethylation reactions within the cell and to inhibit the production of *S*-adenosylmethionine.

Methotrexate

Fig. 90.1 Methotrexate – chemical structure.

Table 90.1 Methotrexate: Mechanisms of action

Suggested mechanism	Rationale
Folate antagonism	Prevents purine and pyrimidine synthesis, required for the proliferation of actively dividing immune cells such as lymphocytes
Inhibition of spermine and spermidine production	Reduces formation of polyamines harmful to tissues
Alteration of cellular redox state	Reversible inhibition of lymphocyte and macrophage functions
Release of adenosine	Generation of a potent endogenous anti-inflammatory mediator through inhibition of catabolism of both adenosine and AMP

S-adenosylmethionine is necessary for the formation of the toxic polyamine metabolites spermine and spermidine, whose accumulation at inflammatory sites is therefore prevented. This inhibition of transmethylation reactions is associated with an impairment of monocyte and lymphocyte function that potentially reduces the subsequent synthesis of reactive oxygen species by these cells. However, diminution of these transmethylation pathways by the *S*-adenosylhomocysteine hydrolase inhibitor deaza-adenosine has failed to produce any beneficial clinical effects in patients with RA.

We and others have shown that methotrexate also exerts its anti-inflammatory effects by releasing an endogenous autocoid, adenosine.² These actions are also attributable to the long-acting polyglutamates formed from the parent compound. As potent inhibitors of the enzyme 5-aminoimidazole-4-carboxamide ribonucleotide (AICAR) transformylase, methotrexate polyglutamates promote the accumulation of AICAR in tissues. Because AICAR inhibits important catabolizing enzymes for both adenosine and AMP (which can be dephosphorylated to adenosine), the net result is an increase in adenosine levels, both intra- and extracellularly. These metabolic pathways are pharmacologically relevant, as aminoimidazole carboxamide and adenosine have been shown to be increased in the urine following low-dose methotrexate treatment in

patients with psoriasis.³ The adenosine thus formed has a multitude of anti-inflammatory functions that include diminution of neutrophil accumulation, adhesion, phagocytosis and generation of reactive oxygen species, inhibition of adhesion molecule expression, suppression of pro-inflammatory cytokines and induction of anti-inflammatory cytokines, as well as modulation of macrophage and endothelial function, as reviewed in detail elsewhere.^{1a} Indeed, blockade of the actions of adenosine at the receptor level reversed the anti-inflammatory effects of methotrexate in animal models. It has also been suggested that caffeine, which is a non-selective antagonist of adenosine receptors, may reduce the effectiveness of methotrexate in patients with RA. Conversely, coffee consumption is known to be protective against the development of cirrhosis of the liver, a major side effect of methotrexate therapy. Much as the release of adenosine is in part responsible for the anti-inflammatory effects of methotrexate, it also contributes to the development of hepatic fibrosis.⁴

ADVERSE EFFECTS

With extensive experience over the years, methotrexate has proved to be one of the safest disease-modifying anti-rheumatic drugs (DMARDs) in current use. Serious side effects such as cirrhosis are much less common than was previously thought (Table 90.2), and clinicians have learned to be cautious about the possible development of adverse events by careful monitoring and co-administration of folic acid, which reduces the occurrence of mucosal and gastrointestinal side effects without limiting the anti-inflammatory activity. Regular blood counts help to identify early signs of cytopenia and minimize their impact. Although mild gastrointestinal side effects such as nausea and vomiting may resolve spontaneously or respond to a dose reduction or folic acid supplementation, mild elevations of serum transaminases rarely necessitate discontinuation of the medication. The risk of serious hepatotoxicity over 5 years of use is likely to be no more frequent than 1 in every 1000 RA patients, although it may be more common in people with psoriasis. Identification of risk factors such as ethanol consumption, hepatitis B and C infection, diabetes, obesity and α_1 -antitrypsin deficiency allow us to exclude patients most likely to develop methotrexate-induced hepatic injury from treatment. However, other serious side effects may be overlooked. For example, early symptoms of pneumonitis, such as a mild cough or shortness of breath, are often ignored. Early identification allows for prompt discontinuation. The risk of developing solid tumours continues to be debated, particularly as the risk of malignancies is intrinsic to some of the conditions for which anti-inflammatory doses of methotrexate are used, such as rheumatoid arthritis. It is likely that this risk is real, as tumor regression following discontinuation of methotrexate has been documented, but the absolute risk remains extremely small.

SULFASALAZINE

It is now all too easily forgotten that sulfasalazine (Fig. 90.2) was originally introduced for the treatment of rheumatoid arthritis in the late 1930s, to a poor reception. It is now applied in a wide range of inflammatory diseases, including inflammatory bowel disease and the seronegative arthritides. Sulfasalazine is a derivative of the anti-inflammatory salicylic acid 5-amino-salicylic acid, as well as the antimicrobial sulfapyridine, as its inventor held the belief that RA had an infectious etiology. These two moieties are joined together by an azo bond. It is unclear

THERAPEUTIC PRINCIPLES

METHOTREXATE

- >> Proven safety profile
- >> Concomitant administration of folic acid advisable
- >> Anti-inflammatory effects may be reduced by heavy use of caffeine
- >> Hepatotoxicity a rare but real concern
- >> Risk of hepatotoxicity increased with:
 - >> Alcohol use
 - >> Hepatitis
 - >> Diabetes
 - >> Obesity
 - >> α_1 -Antitrypsin deficiency

which of the two is principally responsible for the anti-inflammatory actions of the drug, which appear to vary according to disease states. For instance, in inflammatory bowel disease it is likely that 5-amino-salicylic acid, which is poorly absorbed following metabolism by intestinal flora, is the main active component. The mechanism of action in inflammatory

**Fig. 90.2** Sulfasalazine – chemical structure.

arthritis is less clear, although sulfapyridine, which is relatively well absorbed and has a bioavailability in the region of 60%, is likely to play a more important role. Because acetylation is the principal route of metabolism of sulfapyridine following absorption, acetylator status is a major determinant of the plasma half-life. Slow acetylators are also more liable to develop side effects as a result of sulfasalazine therapy.

MECHANISMS OF ACTION

Sulfasalazine has a number of immunomodulatory effects. Both B- and T-lymphocyte proliferation is suppressed *in vitro*. This effect is also seen *in vivo*, as reflected by a decrease in activated lymphocytes in the peripheral blood of patients treated with sulfasalazine. The actions of one of the major proinflammatory cytokines, TNF- α , are also counteracted both by suppression of production of the cytokine, and by inhibition of receptor binding. Sulfasalazine is also a potent inhibitor of the activation of the transcription factor NF- κ B. Like methotrexate, sulfasalazine has inhibitory effects on AICAR transformylase and, as such, promotes the accumulation of adenosine and its anti-inflammatory actions via the adenosine A_{2A} receptor. Consistent with this theory, treatment of animals with an antagonist to the adenosine A_{2A} receptor reversed the effect of sulfasalazine on reduction of leukocyte accumulation in an air-pouch model of inflammation.

ADVERSE EFFECTS

The toxicity of sulfasalazine cannot be overlooked, and in a large series⁵ more than a quarter of those treated over an 11-year period stopped treatment as a result of toxicity. Fortunately, most of these side effects occurred early, were relatively trivial, and resolved after withdrawal of therapy. The most common are minor gastrointestinal symptoms, such as nausea and vomiting or anorexia, and rashes. More serious cutaneous reactions such as exfoliative dermatitis or Stevens–Johnson syndrome are rare. Transaminasemia and drug-induced hepatitis can occur. Blood dyscrasias may arise, including megaloblastic anemia, neutropenia, aplastic anemia and myelodysplastic syndrome. Other adverse effects may involve the neurological system with minor symptoms such as headache or dizziness, or more serious manifestations such as peripheral neuropathy, Guillain–Barré syndrome or transverse myelitis. Sulfasalazine should be

avoided in patients with known allergy to sulfa drugs, and screening for G6PD deficiency should be carried out where appropriate.

AZATHIOPRINE

Azathioprine (Fig. 90.3) is an imidazolyl derivative of 6-mercaptopurine that has been widely used in the treatment of rheumatic diseases such as RA and inflammatory bowel disease, as well as to prevent the rejection of solid organ transplants. Cleavage into 6-mercaptopurine and the imidazole moiety occurs rapidly within erythrocytes, both enzymatically by glutathione transferase, and nonenzymatically. Several enzymes (Table 90.3) participate in the metabolism of 6-mercaptopurine into active and inactive compounds. One of these, thiopurine methyltransferase is known to be associated with genetic polymorphisms in the population, and inherited changes in thiopurine methyltransferase activity may have a strong impact on patient response to azathioprine treatment. Xanthine oxidase is another important enzyme that inactivates 6-mercaptopurine by converting it to 6-thiouric acid. As this occurs mainly in the liver, the importance of first-pass metabolism is best observed in enzyme deficiency states, whether due to disease or to drugs such as allopurinol, where toxicity arising from azathioprine therapy is a major threat.

PROPOSED MECHANISMS OF ACTION

The molecular mechanisms by which azathioprine exerts its immunomodulatory effects are still unclear. As purine analogs, the active metabolites interfere with the *de novo* synthesis of purines and with purine synthesis through the salvage pathway, and are incorporated into RNA and DNA. The proliferation of both T and B lymphocytes is inhibited, and the function of natural killer (NK) cells is also suppressed, without any change in cell numbers. Antibody production is also suppressed, although it is not known which of these effects predominate *in vivo*. Cellular responses to chemoattractants are altered and the production of cytokines such as IL-6 is also affected.

ADVERSE EFFECTS

Azathioprine therapy is generally well tolerated. The most common side effects are gastrointestinal and are generally mild. Pancreatitis may occasionally occur as an idiosyncratic reaction. Hepatotoxicity and cholestasis

Fig. 90.3 Azathioprine – chemical structure.

Fig. 90.4 Cyclophosphamide – chemical structure.

Table 90.3 Principal enzymes involved in the metabolism of azathioprine

Enzyme	Action
Glutathione transferase	Cleaves azathioprine into 6-mercaptopurine and imidazole moieties
Thiopurine methyltransferase	Metabolism of 6-mercaptopurine
Xanthine oxidase	Conversion of 6-mercaptopurine to 6-thiouric acid

are not uncommon, but peliosis hepatis and nodular regenerative hyperplasia occur rarely. The possibility of malignant potential has been raised and there have been reports of a possible heightened risk for non-Hodgkin lymphoma, but these events are rare and no definite link between azathioprine administration and the development of malignancies has been established. Bone marrow suppression and opportunistic infections do occur and pose far greater threats.

CYCLOPHOSPHAMIDE

Alkylating agents were first used in the treatment of inflammatory diseases after promising reports of the application of the first of its kind, nitrogen mustard, in RA. Cyclophosphamide (Fig. 90.4) is a prodrug that is extensively metabolized to produce phosphoryl mustard, an active component responsible for the alkylating actions of cyclophosphamide, as well as acrolein, which is inactive but causes the hemorrhagic cystitis associated with cyclophosphamide therapy. Although it can be given intravenously, bioavailability following oral administration is high (>75%). Its use in inflammatory diseases has been severely limited by toxicity, although it has a useful place in the management of lupus nephritis.

KEY CONCEPTS

MECHANISMS OF ACTION OF SULFASALAZINE

- >> Suppresses the proliferation of lymphocytes
- >> Suppresses proinflammatory cytokine production
- >> Inhibits activation of NF-κB
- >> Promotes adenosine accumulation

MECHANISMS OF ACTION

Cyclophosphamide alkylates guanine residues, principally on DNA, but also on RNA, with the result that strands are rendered cross-linkable and hence the processes of transcription and translation are disrupted. This alkylating process is thought to affect resting as well as actively dividing cells. The number of circulating CD4 T lymphocytes is reduced, and to a lesser extent the number of CD8 T cells is reduced as well, thereby reducing the CD4/CD8 ratio. Despite observations of an increase in immunoglobulin-secreting cells, B-cell function is suppressed and overall immunoglobulin synthesis reduced.

ADVERSE EFFECTS

Perhaps the best-known side effect is hemorrhagic cystitis. As this is known to occur more frequently after oral dosing, this route of administration has fallen out of favor. This may relate to continuous exposure of the bladder to the inactive byproduct acrolein, and the acrolein-neutralizing agent Mesna (2-mercaptoethane sulfonate) has been recommended as a prophylactic measure along with a copious amount of hydration. Hemorrhagic myocarditis may also occur, leading to myocardial necrosis, hemopericardium and congestive cardiac failure. Survivors of acute cardiac toxicity do not, however, appear to show any residual EKG or echocardiographic abnormalities.

Apart from bone marrow suppression, reduction of fertility and a heightened risk of infection as a result of immunosuppression, cyclophosphamide therapy has also been associated with secondary malignancies, which may occur years after cessation of the drug. Malignancies of the bladder, often of a transitional cell type, tend to occur only in those with a previous history of treatment-related hemorrhagic cystitis. Myeloproliferative and lymphoproliferative disorders have also been associated with the use of cyclophosphamide.

LEFLUNOMIDE

A derivative of isoxazole, leflunomide is an inhibitor of *de novo* pyrimidine synthesis. Leflunomide (Fig. 90.5) is an inactive prodrug which is converted into the long-acting active compound A77 1726 (2-cyano-3-hydroxy-*N*-[4-(trifluoromethyl)-butenamide] (Fig. 90.6), which is a reversible inhibitor of dihydro-orotate dehydrogenase, an enzyme involved in pyrimidine synthesis. Because of its long half-life, therapy with leflunomide is usually started with a loading dose so that therapeutic levels can be achieved more quickly. A77 1726 is highly bound to plasma protein and undergoes enterohepatic recirculation.

MECHANISMS OF ACTION

When the synthesis of pyrimidines is inhibited, the availability of pyrimidine nucleotides becomes insufficient to support the growing demands of proliferating immune response cells such as activated T lymphocytes. This deficiency is not adequately replenished by the involvement of salvage pathways, rendering cell proliferation inefficient and thus limiting the clonal expansion of T cells. Proliferation of B cells is similarly suppressed with reduction of Cdk2, a cyclin-dependent

Table 90.4 Adverse effects of thalidomide

Severe	Common	Uncommon or disease specific*

Fig. 90.5 Leflunomide – chemical structure.

Fig. 90.6 A77 1726 – chemical structure.

kinase. Leflunomide also inhibits activation of the transcription factor NF- κ B. Whereas the anti-proliferative actions of moderate concentrations of leflunomide can be reversed *in vitro* by the addition of uridine, this reversal does not occur at higher concentrations, suggesting that at higher concentrations other mechanisms may be important for its immunomodulatory effects. At these higher concentrations, leflunomide inhibits tyrosine kinase activity, although the relevance of this effect *in vivo* remains questionable.

ADVERSE EFFECTS

Liver toxicity is the most important side-effect of leflunomide therapy, although gastrointestinal symptoms appear to be most common. Thus there is some similarity to methotrexate with regard to toxicity profile, and concerns have been raised regarding the co-administration of these two medications. However, clinical trials have shown that these agents can be safely and effectively given together in patients with RA, although transaminasemia occurs more frequently than with methotrexate alone.^{6,7} Occasional episodes of fatal fulminant hepatic failure have been reported. Skin reactions are mostly minor rashes, but occasionally more serious manifestations such as Stevens–Johnson syndrome and toxic epidermal necrolysis occur.

Mycophenylatemofetil

**Fig. 90.7** Mycophenolate mofetil – chemical structure.

MYCOPHENOLATE MOFETIL

Mycophenolate mofetil (Fig. 90.7) has been widely used to prevent rejection in solid organ transplantation, but has also been successfully employed in the treatment of autoimmune diseases such as RA, systemic lupus erythematosus and psoriasis. It is rapidly absorbed and hydrolyzed into the active compound mycophenolic acid, which is a reversible inhibitor of inosine monophosphate dehydrogenase. Because the latter is a key enzyme in the *de novo* synthesis of guanine nucleotides, its inhibition is most keenly felt in lymphocytes, which are more reliant upon the *de novo* synthetic pathway rather than on the hypoxanthine–guanine phosphoribosyl transferase salvage pathway of purine synthesis. The reduction in guanine synthesis has many effects on the immune system. Lymphocyte proliferation is suppressed; antibody production and NK cell activity are also reduced; and *in vitro* cytokine production by activated human mononuclear cells is affected.⁸

ADVERSE EFFECTS

Mycophenolate mofetil is generally well tolerated when used in autoimmune diseases such as RA. The most common side effects are gastrointestinal, such as nausea, vomiting, abdominal discomfort, and diarrhea. Nongastrointestinal side effects include fever, headache, skin rashes, back pain or tremor, but rarely require discontinuation of therapy. Rarer reported side effects include leukopenia and other cytopenias, cutaneous and noncutaneous malignancies, and pancreatitis.

CYCLOSPORINE AND TACROLIMUS (FK506)

Cyclosporine (Fig. 90.8) and tacrolimus (Fig. 90.9) are structurally similar drugs that have been widely used in solid organ transplantation as well as in immunological diseases. Cyclosporine has potent inhibitory effects in damping down the production of proinflammatory mediators such as IL-2 by immunocompetent cells, most importantly T cells. Cyclosporine acts through an association with a binding protein, cyclophilin, which produces a cyclosporine–cyclophilin complex. This complex is a binder of the serine/threonine

**Fig. 90.8** Cyclosporine – chemical structure.

Tacrolimus

**Fig. 90.9** Tacrolimus – chemical structure.

KEY CONCEPTS

MECHANISMS OF ACTION OF CYCLOSPORINE

- >> Association with cyclophilin
- >> Formation of Cyclosporine–cyclophilin complex
- >> Binds calcineurin
- >> Inactivates calcineurin
- >> Regulatory proteins unable to translocate into nucleus
- >> Transcription of proinflammatory genes affected

phosphatase known as calcineurin.⁹ The binding and inactivation of calcineurin disrupts phosphorylation of regulatory proteins, for which NF-AT (nucleated factor of activated T cells) is a critical component. The result is the inability of these proteins to translocate into the nucleus, and the process of transcription of genes important for the promotion of the inflammatory process such as IL-2, which induces mitogenesis in activated T cells, cannot be effectively activated. Several other cytokines are affected, including interleukin-3, interleukin-6, transforming growth factor- β and interferon- γ . Tacrolimus works in a similar way, binding to another T cell-specific immunophilin, FK506-binding protein (FKBP) a tacrolimus-FKBP complex with resultant calcineurin inhibition.¹⁰

ADVERSE EFFECTS

Most patients taking long-term oral cyclosporine will experience a decrease in their glomerular filtration rate,¹¹ and this may lead to a rise in serum creatinine. Some of these may indeed progress to histologically proven nephropathy.¹² Nephrotoxicity has also been a concern during therapy with tacrolimus. Other adverse effects include infections, hepatotoxicity, gastrointestinal upset, rash, tremor, headache and insomnia.

THALIDOMIDE

Historically known primarily for its teratogenic effects, the drug thalidomide (α -[N-phthalimido] glutarimide) has more recently been recognized as a powerful immune modulator and anti-cancer drug. First synthesized in 1954, thalidomide became the drug of choice for pregnant women throughout much of the world for the treatment of morning sickness and nausea. Although initially thought to be completely safe, it soon became apparent that chronic use could cause peripheral neuropathy. More tragically, the drug was also later linked to an epidemic of limb and bowel malformations affecting thousands of children in over 46 nations, resulting in its removal from the world market by 1962.¹³

The serendipitous discovery of thalidomide as an effective anti-inflammatory therapy for erythema nodosum leprosum (ENL) in patients with lepromatous leprosy kept the drug from disappearing completely from the world's formularies. Over the years there were anecdotal reports attesting to thalidomide's efficacy in treating various inflammatory diseases, including Behçet disease, sarcoidosis, Crohn disease and other inflammatory disorders involving the skin and mucosal membranes.¹⁴ In the early 1990s, the discovery that thalidomide was a modulator of cytokine production and blood vessel formation led to a upsurge of interest in its application in immune-mediated diseases, HIV-related conditions and cancer. Approval of thalidomide in the USA was given for the treatment of ENL in 1998 and multiple myeloma in 2005, thus making the drug also available for a multitude of off-label uses by physicians.¹⁵

PHARMACOKINETICS

Thalidomide is a synthetic derivative of glutamic acid, consisting of a glutarimide ring and a phthaloyl ring (Fig. 90.10).¹⁶ Limited in water solubility, thalidomide is administered orally, with variable peak plasma concentrations from a single dose ranging from 3 to 6 hours, and plasma

Thalidomide

Fig. 90.10 Thalidomide – chemical structure.

KEY CONCEPTS

PROPOSED MECHANISMS OF ACTION OF THALIDOMIDE

- >> Tumor necrosis factor- α inhibition
- >> T-lymphocyte co-stimulation
- >> Angiogenesis inhibition
- >> Activation of NK cell responses
- >> Inhibition of cytokine-induced NF- κ B activation
- >> Inhibition of neutrophil and monocyte chemotaxis
- >> Modulation of cell adhesion molecule expression
- >> Inhibition of nitric oxide synthase

half-life between 5 and 14 hours, depending on formulation. Once exposed to an aqueous environment, thalidomide spontaneously and rapidly hydrolyzes into at least 12 hydrolysis products. Having no significant binding to plasma proteins, thalidomide has a large distribution volume and can be found in all bodily fluids, including milk and semen. Most of the absorbed dose is eliminated in the urine, with similar pharmacokinetics observed in renally impaired patients.

PROPOSED MECHANISMS OF ACTION

Despite continued interest in thalidomide over the past half century as a teratogen and immune modulator, its exact mechanism of action remains unclear. The marked species difference in biological effects has suggested that thalidomide may act as a prodrug for one of its hydrolysis products or metabolites. Indeed, although the drug itself is neither a mutagen nor directly toxic to cells, incubation of thalidomide together with liver homogenates or microsomes of rabbit origin produced toxic metabolites that were not found when rodent tissues were used, thereby providing one possible explanation for the species differences in susceptibility to thalidomide's teratogenic effects.

Potential mechanisms to explain thalidomide's biological effects are numerous, suggesting either an as yet undiscovered upstream molecular drug target or a multifaceted mechanism of action. For example, the drug has differential effects on cytokine production, depending on the cell type and stimulus studied.¹⁷ Thalidomide is a broad inhibitor of proinflammatory molecules produced by endotoxin-stimulated monocytes that has been shown to occur by both enhanced mRNA degradation and suppression of NF- κ B activation. However, when a T cell-specific stimulus is used, thalidomide acts through the CD28 pathway

to exert a co-stimulatory or adjuvant effect on T-cell response and downstream Th1 immunity.¹⁸ In addition, thalidomide has been shown to modulate NK cell numbers and activity, cell surface adhesion molecule expression, and nitric oxide synthesis.¹⁹

The identification of thalidomide as an *in vivo* inhibitor of fibroblast growth factor-induced angiogenesis (in the cornea micropocket rabbit model) led to a surge of interest in its use against cancer. In particular, thalidomide has been found effective in treating relapsed and refractory multiple myeloma.²⁰ Proposed mechanisms of action for thalidomide in this disease have included inhibitory effects on bone marrow stromal cell production of IL-6 and TNF- α , important cytokines driving the biology of multiple myeloma.¹⁵ In addition, thalidomide has been shown *in vitro* to activate NK cells to lyse multiple myeloma cells. Potential mechanisms for its effects in solid tumors are less clear.

ADVERSE EFFECTS

Doses of thalidomide reported to be effective clinically range from as low as 25–50 mg/day in cutaneous lupus to 800 mg/day or more in oncology, with the average dosing range for most clinical uses between 100 and 400 mg/day. Adverse effects vary, partly according to dosing levels, but may also be disease specific (Table 90.4). Teratogenicity is the most serious complication, with the period of fetal development sensitive to thalidomide-induced teratogenicity occurring between gestational days 21 and 36. Fetal malformations have been reported with maternal exposure to a single 50 mg dose of the drug. The association of thalidomide with peripheral neuropathies that can be long lasting is another serious side effect that appears unrelated to dose or duration of drug exposure. Sedation, rash, dizziness and constipation are common, but usually self-limiting or clinically manageable. Less common complications include thromboembolism, dry mouth and skin, amenorrhea, neutropenia, bradycardia, weight gain and edema.¹⁹

THALIDOMIDE ANALOGS

The unique biological effects of thalidomide, coupled with its deleterious effects on fetal development and the nervous system, have driven investigators to develop safer thalidomide analogs with logs-fold more potency as immune modulators.^{15, 17} Chemical manipulation of the structure of thalidomide has produced analogs that fall within one of two distinct categories, based on their immune-modulating effects. One group of analogs was noted to be effective inhibitors of endotoxin-induced production of IL-12 and TNF- α by monocytes, but had little effect on other endotoxin-stimulated cytokines. Later investigations revealed that this group achieved its immune-modulating effects through inhibition of phosphodiesterase IV (PDE-4), a well-described anti-inflammatory mechanism by which intracellular cAMP levels are increased. The second group was found, like the parent drug thalidomide, to be broad inhibitors of endotoxin-stimulated production of proinflammatory cytokines as well as having T-cell co-stimulatory effects, albeit having little effect on PDE-4. Currently, clinical trials of the PDE-4 inhibitors have been hampered by dose-limiting side effects, such as nausea and vomiting, common to other drugs of this class. Development of the thalidomide-like analogs has been more successful, resulting to date in the recent approval of lenalidomide (Fig. 90.11) in the USA for the treatment of myelodysplastic syndrome. Lenalidomide has been reported to have reduced sedation and neurotoxicity compared to thalidomide.¹⁵ In addition, this analog has

Fig. 90.11 Lenalidomide – chemical structure.

Fig. 90.12 Imiquimod – chemical structure.

been reported to lack teratogenicity in the New Zealand White rabbit, a model that is susceptible to thalidomide.

IMIQUIMOD

Imiquimod (Fig. 90.12) is an imidazoquinoline drug that is formulated as a dermal cream. It exerts its immune effects by activation of Toll-like receptor-7 and possesses both antiviral and anti-tumor activities.²¹ The antiviral properties have been successfully exploited in the treatment of external genital warts, which are caused by infection with the human papillomavirus. Immune amplification responses are induced through stimulation of inflammatory cytokines, as reviewed extensively elsewhere.^{22, 23} The production of interferon- α is stimulated, which suppresses the replication of viruses in infected keratinocytes. NK cell activity is also increased, partly through the induction of oligoadenylate synthase. The increase of dermal interferon- α transcript levels is both rapid and dramatic.²⁴ Other cytokines modulated by imiquimod include tumor necrosis factor- α and IL-12, peripheral blood monocytes being the principal cell type affected.^{25, 26} The overall effect appears to be a shift from a Th2-cytokine towards a Th1-cytokine predominant profile. Other dermatological conditions where imiquimod has been found useful include actinic keratosis, herpes simplex, basal cell carcinoma and molluscum contagiosum.

ADVERSE EFFECTS

As this is a topical medication, local reactions at the site of application are the most commonly encountered adverse reaction. However, non-dermatological side effects such as fever, fatigue, myalgia and headache have also been described.

Protein kinase antagonists as therapeutic agents for immunological and inflammatory disorders

Arian Laurence, Seth L. Masters, John O'Shea

91

Reversible phosphorylation is one of the major mechanisms controlling protein activity in all eukaryotic cells and as such is involved in all fundamental cellular processes including cell cycle and cell growth, cell shape and movement, metabolism, differentiation, and apoptosis. This covalent modification is a major means for transmitting information from outside the cell and between subcellular components within the cell. Specialized binding domains recognize phosphorylated tyrosine residues on other proteins, and these interactions are used to initiate intracellular signaling pathways.

The importance of protein phosphorylation was well documented by the discovery that mutations and dysregulation of protein kinases play causal roles in human disease. This is especially true in cancer, in which mutant protein kinases or their upstream activators function as oncogenes. Protein phosphorylation is also a major mechanism involved in normal signaling, as exemplified by insulin and other growth factors, whose receptors have intrinsic tyrosine kinase domains. From the point of view of an immunologist, protein phosphorylation is also the major mechanism by which immune receptors, including the T-cell receptor, B-cell receptor, natural killer (NK) and Fc receptors trigger signaling (Chapter 4). The first step in signaling by multichain immune recognition receptors (such as the aforementioned receptors) and co-stimulatory molecules is tyrosine phosphorylation of the receptor itself and adapter molecules like LAT, mediated by Src family protein tyrosine kinases (PTK). This leads to the recruitment of PTK members Syk and Zap-70, followed by phosphorylation of adapters like SLP-76 and the activation of Tec family PTKs. These initial steps lead to activation of serine-threonine kinases, including the mitogen activated protein kinases (MAPKs) and protein kinase C (PKC) family (Fig. 91.1). Many cytokine receptors also initiate signaling by protein phosphorylation (Table 91.1), through the activation of Janus kinases (Jaks, see below: Table 91.2) (Chapter 10). Other cytokines, like tumor necrosis factor (TNF), initiate signaling in a kinase-independent manner, but nonetheless signal through kinase cascades to exert their effects (Chapter 10). We now know a great deal about details through which the cascade of protein phosphorylation links membrane events to calcium modulation, cytoskeletal rearrangement, gene transcription, and other canonical features of lymphocyte action. It is clear that many aspects of protein phosphorylation

are of major importance in immune and inflammatory mechanisms. The absolute requirement for, and in some cases specificity of, different immune cell protein kinases is well exemplified by different knockout mice. Thus, targeting protein kinases could be a useful strategy in the development of novel immunosuppressant drugs. Indeed, targeting kinases is one of the most active areas of pharmaceutical drug development (Table 91.3). The field is so vast that it is impractical to review it comprehensively in one chapter; this chapter therefore focuses on important historical precedents in the field and on targets that are immunologically relevant.

■ STRUCTURE AND FUNCTION OF PROTEIN KINASES ■

Protein kinases or phosphotransferases catalyze the transfer of γ -phosphate of a purine nucleotide triphosphate, (i.e., adenosine triphosphate (ATP) and guanosine triphosphate (GTP)) to the hydroxyl groups of their protein substrates. They generate phosphate monoesters using protein alcohol groups (on serine and threonine residues) and/or protein phenolic groups (on tyrosine residues) as phosphate acceptors. Thus, protein kinases can be classified by the amino acid substrate preference: serine/threonine kinases, tyrosine kinases, and dual kinases (meaning that both serine/threonine and tyrosine residues can be phosphorylated). Almost all protein kinases have catalytic domains that belong to a single eukaryotic protein kinase (ePK) superfamily. The common evolutionary ancestry of the kinase domain (also known as the catalytic domain), which consists of 250–300 amino acid residues, manifests as a highly conserved three-dimensional structure. There are 518 kinases in the human genome divided into eight major groups, which in totality represent 1.7% of the human genome. The PTK family has 90 members, one-third of which are receptor tyrosine kinases (RTK) and the remainder are cytoplasmic proteins that typically function in close proximity to, and downstream of, receptor–ligand complexes.

In terms of its catalytic role, the kinase domain has three functions: (1) the binding of the ATP (or GTP) phosphate donor as a complex with a divalent cation (usually Mg^{2+} or Mn^{2+}); (2) the binding of the protein

substrate; and (3) the transfer of the γ -phosphate from ATP or GTP to the protein substrate. Despite the huge number of serine/threonine and tyrosine kinases, there is evidence of a common ancestor and this is reflected in structural similarities, particularly in the active (ATP-bound) confirmation. The major kinase domains of all typical protein kinases consist of two lobes (N-lobe and C-lobe) that surround the nucleotide binding site¹ (Fig. 91.2). The smaller N-lobe consists of a cluster of β -pleated sheets with a single α -helix. The larger C-lobe is made up of α -helices. Within the C-lobe lies the substrate-binding site, typically a groove on the surface. A hinge region connects the two lobes. The hinge, together with two loops emerging from each lobe, forms the ATP binding pocket: the primary target for most kinase inhibitors. In many protein kinases a loop emerging from the C-lobe must be phosphorylated in order for the kinase to be fully active (Fig. 91.2). This is known as the activation loop. Substrates of PTKs often include the activation loop of downstream kinases, creating signaling cascades of proteins that in turn phosphorylate each other; examples include the MAPKs (Fig. 91.3).

A SHORT HISTORY OF THE FIRST-GENERATION KINASE INHIBITORS

Given that protein kinases bind ATP, the notion that therapeutically useful kinase inhibitors could be generated initially met with some skepticism. First, as there are more than 500 human kinases, many of which serve critical cellular functions, would it really be possible to attain the

KEY CONCEPTS

PROTEIN KINASE SUPERFAMILIES (1.6% OF THE GENOME)

- >> Protein tyrosine kinases (90 members, e.g., Jak3)
- >> Protein serine/threonine kinases (400 members)
- >> AGC kinase family (e.g., protein kinase B/Akt)
- >> CAMK kinase family (e.g., calmodulin-dependent kinase)
- >> CMGC kinase family (e.g., MAP kinases: ERK, JNK, p38)
- >> STE kinase family (e.g., MAPKK kinases, MAPK kinases)
- >> TKL kinase family (e.g., IRAK)
- >> Others: casein kinase family, GYC kinase family, IKK family

specificity needed? Second, protein kinases are not the only kinases – there are lipid kinases and nucleotide kinases, in addition to numerous other types of ATP-binding proteins. Third, despite the many potential ways of designing a small-molecule kinase inhibitor, in practice the existing successful inhibitors all work by sitting within the ATP-binding pocket.² *A priori*, then, one might conclude that it would be impossible to generate an antagonist that did not target some other essential ATP-dependent process. Fortunately, though, this dismal view does not reflect reality.

Table 91.1 The common γ chain receptor family of cytokine receptors

Cytokine receptor	IL-2R	IL-4R	IL-7R	IL-9R	IL-15R	IL-21R
Functions	Control of peripheral self tolerance (mice)	Regulation of B-cell function (in concert with IL-21 and IL-25)	Thymocyte survival and development factor	Goblet-cell hyperplasia	CD8 ⁺ memory T-cell survival and proliferation factor	T- and B-cell proliferation factor
	Development and maintenance of T-regulatory cells	Immunoglobulin class switching	Peripheral T-cell survival factor. Mediates homeostatic reconstitution of lymphopenic animals	Mucus production	Peripheral T-cell survival factor. Mediates homeostatic reconstitution of lymphopenic animals	Regulates immunoglobulin production (with IL-4)
	Differentiation of helper and cytotoxic T cells	Differentiation of helper T cells (Th2 lineage)	B-cell progenitor survival factor (mice)		NK cell development, differentiation, and survival factor	NK cell proliferator and activation factor
	<i>In vitro</i> expansion and differentiation of antigen-selected T and NK cells	Co-stimulant for growth in T, B, and mast cells				Differentiation of helper T cells (Th17 lineage)
		Inhibition of Th1 differentiation and macrophage activation				
Downstream signaling pathways	PI3K, Ras, MAPK, STAT1, 3, 5	PI3K, Ras, MAPK, STAT 5, 6	PI3K, STAT(1), (3), 5	PI3K, Ras, MAPK, STAT1, 3, (5)	PI3K, Ras, MAPK, STAT1, 3, 5	PI3K, Ras, MAPK, STAT1, 3,(5)

IL, interleukin; MAPK, mitogen activated protein kinases; NK, natural killer.

Table 91.2 The Jak family of tyrosine kinases

Gene	Phenotype associated with gene deletion or mutation	Associated receptor
Jak1	Perinatal lethality, block in thymocyte development	Many, including IL-7R and IFN receptors
Jak2	Embryonic lethality due to anemia	Many, including the Epo receptor
Jak3	T, B, NK-cell lymphopenia, SCID phenotype	Common γ -chain receptor
Tyk2	Failure to clear <i>Toxoplasma</i> , reduced arthritis	Many, including the IL-12/23 receptor and the IFN α receptor

IFN, interferon; IL, interleukin; Jak, Janus kinase; NK, natural killer; SCID, severe combined immunodeficiency.

Table 91.3 Selected kinase inhibitors and related drugs

Mechanism	Compound	Kinase inhibited	Comments
Direct binding to the kinase	Imatinib	KIT, PDGFR, and Bcr-Abl	Licensed for the treatment of CML, eosinophilic leukemia and gastric stromal tumors. Under evaluation in multiple types of cancer and in combination with other cancer drugs
	Erlotinib	VEGFR-2 and EGFR tyrosine kinases	In phase III trials for treatment of advanced nonsmall-cell lung cancer.10/05: Granted orphan drug designation by the FDA for treatment of certain rare forms of thyroid cancer. Erlotinib is in phase II development for treatment of medullary thyroid cancer. Also in clinical development for treatment of additional cancers
	Sorafenib	Dual specific inhibitor blocking both tyrosine and serine / threonine kinases including: RAF kinase, VEGFR-2, VEGFR-3, PDGFR-B, KIT, and FLT-3	FDA-approved for treatment of advanced renal cell carcinoma. Also being developed for treatment of additional cancers. Phase III trial in nonsmall-cell lung cancer planned
	Dasatinib	Multiple Src family tyrosine kinases, including BCR-Abl	Filed for approval for treatment of adult CML and Philadelphia chromosome-positive ALL
	Lestaurtinib	FLT3 and Trk	In phase II clinical trials for treatment of AML patients who have an FLT3-activating mutation at first relapse from standard induction chemotherapy
Indirect binding to kinase	Lapatinib	ErbB-2 and EGFR kinases	For treatment of breast cancer. Also in development for treatment of renal, gastric, and head and neck cancers
	Sunitinib	Inhibits multiple RTKs including PDGFR3- α , PDGFR- β , VEGFR1 VEGFR2, VEGFR3, Kit, FLT3, CSF-1R, and RET	For treatment of gastrointestinal stromal tumor after disease progression on or intolerance of imatinib mesylate, and for treatment of advanced renal cell carcinoma
	CP-690 550	Jak3	Efficacy shown in animal models of solid-organ transplantation and chronic graft-versus-host disease
	SCIO 469	p38 MAPK	Phase II trials starting in the treatment of rheumatoid arthritis
	VX-702	mTOR	Phase II trials ongoing in rheumatoid arthritis and myeloma
	Sirolimus (Rapamycin)		Phase II trials ongoing in rheumatoid arthritis
	Temsirolimus		Licensed for use in solid-organ and bone marrow transplantation
	Everolimus		Phase II clinical trials in the management of mantle-cell lymphoma. A 38% response rate has been reported
	Trastuzumab	EGFR-2	Small benefit in advanced renal cell carcinoma – currently being fast-tracked by FDA
	Pertuzumab	EGFR	Phase II clinical trials ongoing in multiple sclerosis and rheumatoid arthritis
Monoclonal antibodies binding to receptor tyrosine kinases	Cetuximab	VEGF – prevents binding to its receptor (FLT-1)	Licensed for use with cyclosporine in cardiac and renal transplantation. Clinical trials are assessing its use in rheumatoid arthritis
	Bevacizumab	Farnesyl transferase (Ras – MAPK)	Licensed for use in relapsed colorectal cancer in combination with traditional chemotherapy
	Tipifarnib		Licensed for use in HER2/neu-positive breast carcinoma
	Other indirect inhibitors of kinase signaling pathways		Prevents dimerization of the receptor – undergoing phase I/II studies in solid tumors
			Licensed for use in relapsed colorectal cancer in combination with traditional chemotherapy
Other indirect inhibitors of kinase signaling pathways	Tipifarnib	Farnesyl transferase (Ras – MAPK)	Fasnylation inhibitor: inhibits formation of farnesylated signaling proteins (Ras). Phase II clinical trials for MDS/AML

The stem '-inib' denotes a tyrosine kinase inhibitor; '-rolimus' denotes a macrolide immunosuppressant. ALL, acute lymphoblastic leukemia; AML, acute myeloid leukemia; CML, chronic myeloid leukemia; EGFR, epidermal growth factor receptor; FDA, Food and Drug Administration; MDS, myelodysplastic syndrome; PDGFR, platelet-derived growth factor receptor; VEGFR, vascular endothelial cell growth factor receptor.

Fig. 91.2 Crystal structure of the Jak3 kinase domain complexed with staurosporine (pdb accession code 1YVJ). This structure captures the active conformation of Jak3 with both active-loop tyrosine residues phosphorylated (green). The molecule can be described in two halves, with the N-terminal lobe presented in blue and the C terminal domain in red. These are linked by a hinge region that forms part of the active site. Highlighted in magenta within the active site is the gatekeeper residue. Bound within this site is an analogue of the inhibitor staurosporine, and its proximity to the gatekeeper residue highlights why this residue and this region are critical for the specificity of inhibitors for individual protein kinases.

IMATINIB AND OTHER FIRST-GENERATION PROTEIN TYROSINE KINASE INHIBITORS

The first Food and Drug Administration (FDA)-approved protein kinase inhibitor is imatinib (Table 91.3). The mutated form of the Abl tyrosine kinase, BCR-Abl, represents a fusion protein that is the result of a chromosomal translocation (Philadelphia chromosome) observed in patients with chronic myeloid leukemia (CML).³ The pathognomonic presence of BCR-Abl in CML has led to it becoming one of the most intensively studied PTKs. The fusion protein consists of an oligomerization domain, a pleckstrin homology (PH) domain and a Dbp/cdc24 guanine nucleotide exchange factor homology domain that contains the N-terminal breakpoint cluster region (BCR) of the protein. The Abl half of the fusion protein contains a tyrosine kinase domain, a Src homology 2 (SH2) domain, and a DNA-binding domain together with nuclear localization and nuclear export motifs. The Abl kinase is constitutively active within the fusion protein and has been implicated in initiating numerous signaling pathways that mediate cell survival and proliferation. In view of this and the essential requirement for BCR-Abl kinase activity in CML, it was thought to be an ideal target for the generation of a selective kinase inhibitor despite the aforementioned caveats with targeting protein kinases. As predicted, imatinib has revolutionized the treatment of CML. This inhibitor has been remarkably successful in arresting the progression of the disease, but is also well tolerated with minimal side effects.

The epidermal growth factor receptor (EGFR) is another intensively studied PTK which is highly expressed and/or frequently mutated in cancers. It too has been considered a good therapeutic target and gefitinib was the first selective EGFR inhibitor. Gefitinib was not efficacious in a nonsmall-cell lung cancer trial; however, erlotinib, another EGFR inhibitor, has been approved by the FDA for the treatment of pancreatic and nonsmall-cell lung cancer.

Fig. 91.3 A summary of the mitogen activated protein kinases (MAPK) signal transduction pathways. Examples of receptors that activate Ras include the interleukin-2 (IL-2) receptor and T-cell receptor; examples of receptors that activate TRAF6 include the IL-1 receptor.

While conservation of the kinase ATP-binding pocket has posed a potential problem for designing kinase inhibitors, in practice this has not happened for a number of reasons. Although different kinases are structurally similar in an active ATP-bound conformation, this is not so in the inactive conformation – a form that is exploited by many selective inhibitors.⁴ The ATP-binding region is made up of six polar amino acid residues that are invariant across whole families of kinases; similarly, there are a number of lipophilic residues that are highly conserved, but within this critical region lies an amino acid with an amide carbonyl that binds to N-6 of adenine in the active conformation. The side chain of this amino acid sticks into the reaction pocket in the inactive state and for this reason is referred to as the ‘gatekeeper’ residue. As the side chain is not involved in direct ATP binding, it varies across kinases, and variation of this gatekeeper residue is exploited by a number of inhibitors that are able to bind the inactive conformation of specific kinases. In the case of Abl kinase the gatekeeper residue is threonine, which binds directly to a methyl group of the phenyl ring of the Abl kinase inhibitor imatinib.⁴ Across the collective kinase superfamily almost any amino acid can appear as the gatekeeper, although in practice it is typically a bulky nonpolar residue (methionine, tyrosine, phenylalanine, lysine). Clearly, as more detailed structural information emerges from the many protein kinases, capitalizing upon subtle differences in structure, in principle, would be expected to improve potency and specificity. For instance, cyclin-dependent kinase 2 (CDK2) contains an additional pocket on its C-lobe next to the ATP-binding pocket.⁵ A number of CDK2-specific inhibitors exploit this by binding to both pockets.

Of further structural significance is the emergence of tumor drug resistance in response to the chronic use of protein kinase inhibitors. Mutant forms of BCR-Abl, Kit, and EGFR have been associated with loss of drug activity and disease relapse. Interestingly, one of the most common sites of mutation is the otherwise conserved gatekeeper residue. Although a major problem in the treatment of malignancy, this is less likely to be an issue in the treatment of autoimmune disease.

One of the surprises that has emerged regarding imatinib is that, although it was originally thought to be a highly specific inhibitor for Abl kinase, in reality it does have activity against other PTKs.⁶ Consequently, it has been found to be useful in the treatment of other tumors and this has led to its successful use in the treatment of gastrointestinal stromal tumor, and hypereosinophilic syndrome through its effects on Kit⁷ and platelet-derived growth factor receptor (PDGFR)-FIPIL1⁸ kinases respectively. In spite of efforts to develop highly specific kinase inhibitors, there is increasing evidence that a partial inhibition of multiple kinases is efficacious and is potentially less toxic than originally feared. One such broad-spectrum kinase inhibitor is the recently FDA-approved inhibitor sorafenib for use in advanced renal cancer. Sorafenib inhibits the serine/threonine kinase Raf, as well as RTKs, including PDGFR, vascular endothelial growth factor receptor (VEGFR), Kit, and FLT-3.

Many receptors, including RTK, such as EGFR and PDGFR, activate the MAPK signaling pathway via the small p21 GTPase Ras. The MAPK family consists of numerous serine/threonine kinases that can be crudely divided into three groups: (1) the MAPKs themselves; (2) kinases that phosphorylate the MAPKs, the MAPK kinases (MKKs); and (3) the MKK kinases (MKKKs) (Fig. 91.3). Not only is Ras activated by a number of growth factors, but it is also frequently mutated in cancers. Ras activation leads to the activation of the MKKK, Raf. This in turn phosphorylates the MKK, MEK which subsequently phosphorylates and activates the MAPKs ERK1 and 2. Two small-molecule

inhibitors of this serine/threonine kinase pathway are undergoing clinical trials: the farnesyl inhibitor of Ras, tipifarnib, in the management of myelodysplasia, and the multikinase inhibitor sorafenib for the treatment of renal cell carcinoma. Sorafenib inhibits the MKKK Raf, as well as RTKs, including PDGFR, VEGFR, Kit, and FLT-3, and is approved by the FDA for the treatment of hepatocellular and renal carcinoma.

Although only four small-molecule kinase inhibitors are FDA-approved for various malignancies at this time, many other candidates against a range of kinases are being tested in the clinic presently. Additionally, though, another class of kinase antagonists exists. These are antibodies that are directed against extracellular domains of RTKs. These include cetuximab, panitumumab, trastuzumab, ranibizumab and bevacizumab, which are directed against the EGFR, Her2/Neu, VEGFR, respectively. Pertuzumab, one of the first in a new class of targeted therapeutic agents known as heterodimerization inhibitors (HDIs), is currently being evaluated in clinical trials in the treatment of lung, ovarian, and prostate cancer. It has passed phase I studies that have confirmed its safety but phase II trials in nonsmall-cell lung cancer have to date been disappointing.⁹

In summary, oncology studies have demonstrated unequivocally the safety and efficacy of inhibiting kinases either through small molecules or, in the case of RTKs, with antibodies.

TARGETING IMMUNE CELL KINASES

The development of therapeutically useful kinase inhibitors for the treatment of immune and inflammatory disease is also an area of intensive research. Although at present there is only one class of kinase inhibitors approved by the FDA for the treatment of immune-mediated disease, the expectation is that many more will follow.

mTOR INHIBITORS

As its name suggests, mammalian target of rapamycin (mTOR) can be inhibited by the macrolide, rapamycin, now licensed for use against graft rejection as the drug sirolimus¹⁰ (Fig. 91.4). mTOR is a critical link in coupling cell growth stimuli with cell cycle progression. It is activated by a number of growth factor receptors, including the interleukin-2 (IL-2) receptor in T cells. Many signaling pathways link growth factor receptors with activation of mTOR, including the AMP-dependant kinase (AMPK), phosphatidylinositol 3' kinase (PI3'K)¹¹, and MAPK pathways (discussed below) (Fig. 91.4). mTOR promotes cell growth by activation of p70 S6K1 and inactivation of 4EBP-1.¹² Critical to cell growth is the translation of new protein. This process is initiated by the multi-subunit complex eIF4F; unphosphorylated 4EBP-1 represses the eIF4F complex by binding to one of the subunits, eIF4E. mTOR phosphorylates and inactivates 4EBP-1, allowing the initiation of protein translation. Maintenance of protein translation is further regulated by the phosphorylation of the 40S ribosomal subunit S6. Once phosphorylated, S6 can be recruited to actively translating polysomes; this is performed by the serine/threonine kinase p70 S6K1, which is itself phosphorylated and activated by mTOR.

Sirolimus does not inhibit mTOR by direct binding to the ATP-binding pocket but acts indirectly, associating with FK506-binding

Fig. 91.4 Signal transduction pathways stemming from the interleukin-2 receptor in T cells culminating in the activation of the mTOR serine/threonine kinase. Tyrosine kinases are indicated in red and serine/threonine kinases are indicated in blue.

protein 12 (FKBP12). This in turn inhibits the kinase complex made up of mTOR, mLST8, and raptor (mTORC1).¹³ Sirolimus was hoped to be a potent anticancer drug but has met with limited success in this regard. In contrast it has been successfully used as an immunosuppressant typically as part of a combination regimen for allograft rejection prophylaxis.

In a US phase III study sirolimus was compared with azathioprine in patients receiving prednisolone and cyclosporine for renal graft rejection prophylaxis.¹⁴ After 6 months there was a 17% incidence of graft failure in the sirolimus group and a 32% incidence in the azathioprine group, although after 12 months there was no significant difference between the

two groups.¹⁴ Further studies have compared sirolimus with cyclosporine in conjunction with mycophenolate and prednisolone in renal transplantation and generally found equivalence.¹⁵ There is more limited experience with sirolimus in transplantation of other solid organs, although it is being used in heart, lung, liver, and pediatric intestinal transplantation. Finally, sirolimus is being used as a second-line agent in the treatment of graft-versus-host disease in bone marrow transplantation.¹⁶

In view of the ubiquitous expression of mTOR and its role in protein translation, it is not surprising that sirolimus would be associated with varied side effects; these include hyperlipidemia, hypertriglyceridemia, myelosuppression, and delayed wound healing.¹⁷ There is some evidence

of renal toxicity but this is minor compared with the calcineurin inhibitors cyclosporine A and tacrolimus. This has made sirolimus an attractive agent in renal graft prophylaxis and in other patients where long-term use of calcineurin inhibitors has resulted in renal impairment. A multicenter prospective study has suggested a twofold increased risk of a surgical complication in cardiac transplant patients on sirolimus compared with mycophenolate.¹⁸ These two findings have led groups to consider avoiding sirolimus early on in renal transplantation but to introduce it later as an alternative to a calcineurin inhibitor so as to avoid chronic allograft nephropathy.¹⁹ Myelosuppression associated with sirolimus is typically dose-related and rapidly reversible, even in patients receiving the drug for chronic graft-versus-host disease.¹⁶

There are currently three rapamycin derivatives undergoing clinical trials: temsirolimus, everolimus, and AP23573. Everolimus is licensed for use in the management of cardiac and renal transplantation in conjunction with cyclosporine; it is being investigated in the treatment of rheumatoid arthritis. Temsirolimus is showing promise as an anti-mantle-cell lymphoma agent²⁰ and in the management of rheumatoid arthritis and multiple sclerosis where phase II trials have reported a 50% reduction in development of lesions on magnetic resonance imaging over a 9-month period.²¹

JAK3 INHIBITORS

Cytokines regulate growth, survival, development, and differentiation of immune cells. Their critical importance in organizing inflammatory and immunological responses has made them attractive targets for anti-inflammatory and immunosuppressive agents. A large subset of cytokines signal through a small family of PTKs called Janus kinases, or Jaks, which associate with these receptors²² (Table 91.2). Cytokine binding leads to the phosphorylation of the Jaks themselves and the cytokine receptor subunits.²³ This phosphorylation step is critical for the initiation of subsequent signaling.

T-cell activation and development are highly dependent upon a subfamily of cytokines, IL-2, 4, 7, 9, 15, and 21, that share a common receptor subunit termed the common gamma chain (γ_c) (Table 91.1)²⁴ (Fig. 91.4) (Chapter 10). γ_c associates with a specific Janus kinase, Jak3. Deficiency of the γ_c or Jak3 results in a severe combined immunodeficiency in both mouse and humans characterized by an almost complete absence of T cells and NK cells with defective B-cell function^{24, 25} (Chapter 35). It is important to note that no other organ is affected by the defect, suggesting that, unlike many other cytokines, the actions of the IL-2R γ_c family of cytokines are restricted to hematopoietic cells.

The selective expression of Jak3 and the potent immunosuppression associated with its deletion in humans and mice have made it an ideal target for drug development. Considerable effort has been made in generating selective Jak3 inhibitors. One oral potent Jak3 antagonist, CP-690,550, has been most intensively studied. CP-690,550 was efficacious in preclinical transplant models both as a single agent and in combination with mycophenolate.²⁶ A phase II clinical trial investigating the role of CP690,550 in rheumatoid arthritis is under way.

CP-690,550-treated primates developed a reversible lymphopenia. Little reduction in CD4 T cells was seen, but significant reduction in NK cells and CD8 T cells was evident; just how significant this will be in terms of infection risk remains to be determined.²⁷ Because of the importance of IL-2 for differentiation of regulatory T cells, it is conceivable that a Jak3 antagonist could exacerbate autoimmune disease. However, monoclonal antibodies directed against IL-2R α (CD25) (daclizumab and basiliximab) have been successfully used in combating both acute transplant rejection

CLINICAL PEARLS

PRINCIPAL CAUSES OF SEVERE COMBINED IMMUNODEFICIENCY AND DRUGS THAT MIMIC THESE CONDITIONS

- >> Common γ -chain deficiency
- >> No drug mimic, although the interleukin-2 receptor can be blocked by daclizumab
- >> Jak 3 kinase deficiency
- >> Mimicked by CP-690, 550
- >> Adenosine deaminase deficiency
- >> Mimicked by cladribine and fludarabine

and graft-versus-host disease, apparently without precipitating an autoimmune state analogous to the IL-2-deficient mouse.²⁸ Conversely, IL-21 has recently been reported to have a role in inducing IL-17 secretion in mouse CD4 T cells. These cells have been associated with a number of autoimmune disease models in mice and have been implicated in their equivalent diseases in humans. CP-690 550 could potentially inhibit this induction. CP-690,550 therapy is associated with a neutropenia and a dose-dependent anemia.²⁶ The latter is probably due to inhibition of Jak2, which is essential for erythropoietin signaling. Interestingly, there is some evidence that aberrant Jak3 signaling contributes to leukemogenesis in both mouse and humans.²⁹ We may yet come to see Jak3 antagonists used as a possible anti-leukemia therapy in selected cases, despite its effects on NK cells.

OTHER TARGETS TO CONSIDER FOR NOVEL IMMUNOSUPPRESSANTS

As discussed, a plethora of information exists pertaining to the role of different kinase-dependant signaling pathways in mediating signals from immunologically relevant receptors. Consequently, many of these kinases represent reasonable targets to consider in generating new immunosuppressive agents.

ANTIGEN AND ANTIGEN/ANTIBODY ACTIVATED TYROSINE KINASES

As noted above, early events in T-cell receptor signaling include the activation of Src family kinase Lck, Zap-70, and Tec family PTKs (Fig. 91.1). For other immune receptors, such as Fc receptors, the Src family kinases Lyn and Syk are key components of signaling. Despite much effort and a wealth of basic information, a clinically useful Src-family kinase has not been identified. Like Jak3, the downstream tyrosine kinase Zap-70 is only expressed in T and NK cells and its deficiency results in severe combined immunodeficiency. Although a selective inhibitor has not yet been generated, it remains a very attractive target, not only as a potential immunosuppressive but as a treatment for chronic lymphocytic leukemia (CLL); unlike normal B cells, CLL cells can express ZAP-70 and its presence is associated with a poor prognosis.³⁰

Another group of antigen receptor-associated kinases is the Tec family. One member, Btk, is expressed in B cells and granulocytes, where its absence causes Bruton's agammaglobulinemia in humans and a similar condition in mice (Chapter 34). This is characterized by a complete absence of B cells and plasma immunoglobulins but preservation of T- and NK-cell function. Patients require regular infusions of intravenous immunoglobulin, but once on this therapy are otherwise healthy. This makes Btk an attractive target for the treatment of antibody-mediated immunological disorders, including the autoimmune hemolytic anemias, thrombocytopenias, myasthenia gravis, immune complex diseases, and the numerous B-cell malignancies. Preliminary work on the Btk inhibitor LFM-A13 has suggested that this agent causes a neutrophil defect but it is uncertain whether this is due to poor selectivity of the inhibitor or a direct effect of inhibiting Btk in neutrophils.³¹ Three other members, Itk, Rlk, and Tec, are expressed in T cells. Mouse knockout studies suggest the usefulness of potential inhibitors:³² Itk knockout mice show defects in Th2 development and are resistant to induction of asthma where they exhibit less eosinophil pulmonary infiltration. Conversely, Rlk-deficient mice have a Th1 developmental abnormality.

PROTEIN KINASE C FAMILY

The stimulation of antigen receptor-associated kinases culminates in the activation of several serine/threonine kinase signaling pathways, including the activation of PKC family kinases. The importance of individual PKC members has partially been elucidated by the use of knockout mice models. The removal of one such member, PKC- θ , results in T cells that produce less IL-2 and are less able to proliferate in response to T-cell receptor stimulation.³³ PKC- θ has since been linked to the activation of the NF- κ B complex.³⁴ NF- κ B is a critical regulator of many cytokines and is also involved in the regulation of cytokine production. Targeting the kinases that lead to NF- κ B activation is another area of intense investigation. The importance of PKCs in the pathophysiology of malignancy has aided the search for potential inhibitors, although their ubiquitous expression casts doubt as to whether a nontoxic inhibitor will be discovered. The proteasome inhibitor bortezomib, licensed for use in myeloma, is thought to block the action of NF- κ B. Its properties as an immunosuppressant have not been investigated.

LIPID KINASES AND DOWNSTREAM SIGNALING

Kinases are also important in phosphorylating lipids and these modifications are very relevant in signal transduction through both T-cell receptors and cytokine receptors. Of particular interest are phosphatidylinositol (PI) kinases, including PI3' kinases; although their substrate is a lipid, these kinases share a close homology with protein kinases. Specifically, these enzymes phosphorylate the 3' position of phosphatidyl 4,5 bisphosphate to form phosphatidyl 3,4,5 triphosphate (PIP₃).³⁵ Abundant studies document the importance of PIP₃ and PI3'K immune cell activation, and two PI3'K inhibitors of class I PI3'Ks that have been widely used for research are Ly294002 and Wortmannin.³⁶ However, toxicity prevents either from being clinically useful. In contrast to the more widely expressed PI3'K α and β , PI3'K γ is only expressed in hematopoietic tissue³⁷ and deletion of PI3'K γ results in defective migration of neutrophils and macrophages to sites of inflammation without other pathology.³⁸ This limited expression makes PI3'K γ a potentially useful target and selective

PI3'K γ inhibitors are effective in inhibiting murine collagen-induced arthritis.³⁹

Generation of PIP₃ activates the serine kinase protein kinase B (PKB or Akt) and PIP₃-dependent kinase 1 (PDK1). The latter is known to phosphorylate the activation loop of many AGC family kinases and is critical for their subsequent activation.⁴⁰ Specific inhibitors of PKB are being intensively sought by a number of pharmaceutical companies. Complete deletion of PDK1 is embryonically lethal in mice but a partial deletion is not; animals are small, viable, and lymphopenic.⁴¹ This observation suggests that a potential PDK1 inhibitor, despite its broad range of targets, might be a useful immunosuppressant.

MAPK PATHWAYS

MAPK pathways are activated by multiple immunologically relevant receptors and there are currently numerous small molecules in development to inhibit both directly and indirectly protein kinases of the MAPK family, some of which have been specifically designed as immunosuppressants.

A distinct MAPK signaling cascade was discovered by virtue of the drug inhibitors that affect this pathway. A group of pyridinyl-imidazole inhibitors were identified as cytokine synthesis anti-inflammatory drugs. Their molecular targets were subsequently identified as the p38 MAPK family, a group of four MAPKs (p38 α - δ) with structures similar to the ERKs. Activation of monocytes with lipopolysaccharide induces the p38 MAPK pathway, leading to secretion of the inflammatory cytokines TNF- α and IL-1.⁴² The success of anti-TNF- α agents has illustrated the importance of this cytokine in the pathophysiology of rheumatoid arthritis.

Although these drugs were discovered more than 10 years ago, there is no FDA-approved p38 inhibitor on the market. Several have been tested, including AMG 548 and BIRB 796, but they have been abandoned due to toxicity.⁴³ Two more agents, SCIO 496 and VX 702, are undergoing phase II trials in the treatment of rheumatoid arthritis and Crohn's disease, but it must be recognized that the p38 MAPKs are both ubiquitous and conserved throughout evolution from yeast to mammals; in this respect such a target is not ideal.

In addition to being activated by growth factor receptors, Ras and Raf are activated by a number of cytokine receptors, including IL-2R and T-cell receptors.⁴⁴ Mice lacking either ERK1 or its downstream target SAP-1⁴⁵ demonstrate a profound defect in thymocyte positive selection. Thus, it is conceivable that drugs that target this pathway may be considered for use as immunosuppressives, with the caveat that inhibition of the Ras/MAPK pathway could have significant nonimmunological effects.

RECEPTOR TYROSINE KINASES

The anti-cancer monoclonal antibodies cetuximab and trastuzumab act by preventing the dimerization of the EGFR receptor tyrosine by binding to the extracellular domains of the receptor. An immune-specific RTK could be a target for antibody therapy; however, to date, no obvious candidate has emerged. Parenthetically, as discussed previously, the IL-2 receptor is a heterotrimeric complex that associates with Jak family tyrosine kinases. The monoclonal antibodies daclizumab and basiliximab bind to the IL-2R α chain; although this receptor has no kinase domain, these monoclonal antibodies prevent activation of the receptor by IL-2. It is licensed in the treatment of organ rejection and acute graft-versus-host

THERAPEUTIC CONCEPTS

MECHANISMS OF KINASE INHIBITOR SPECIFICITY

- >> Gatekeeper residue within the kinase reaction pocket
e.g., Imatinib binding to Abl kinase
- >> Unique subsidiary binding pockets near the kinase reaction pocket
e.g., Cyclin-dependent kinase 2
- >> Specific protein-binding partners that can be blocked
e.g., Sirolimus/FKBP12 inhibition of the mTOR–mLST8–Raptor complex
- >> Inhibition of kinase activation by upstream signaling
e.g., Inhibition of Ras-dependent kinases by tipifarnib

disease. Clinical trials are assessing its efficacy in the treatment of multiple sclerosis and Crohn's disease.

CONCLUSION

The success of the anti-cancer BCR–Abl inhibitor imatinib and the immunosuppressive mTOR inhibitor sirolimus has placed the protein kinases center stage as targets of future drug discovery. A primary focus of efforts by drug companies is the development of novel anti-cancer drugs, but as we have seen with sirolimus, many of the kinases central to tumor cell proliferation are also important in T-cell activation. Conversely, inhibition of Jak3 could potentially be used in the treatment of leukemia. Either way, we are likely to see a number of novel immunosuppressants appear both serendipitously and intentionally as new protein kinase inhibitors are developed for a wide range of debilitating illnesses.

Vaccines

Alan R. Shaw, Mark B. Feinberg

92

Vaccines represent one of the most effective and cost-effective medical and public health achievements of all time.¹ Worldwide, vaccination programs are currently estimated to save over 3 million lives each year. In addition to having such a major beneficial impact on vaccine-preventable disease morbidity and mortality, the direct and indirect impacts of vaccination programs translate into economic savings of many billions of dollars each year. In what is considered to be one of the most significant medical successes of all time, a collaborative and comprehensive vaccination campaign against smallpox resulted in the global eradication of the disease in 1979.² Similarly, efforts to eradicate poliomyelitis have made tremendous progress in reducing the global disease burden, and will hopefully soon overcome certain residual societal and programmatic obstacles to provide the second successful example of elimination of a major health threat by vaccination. Concerted global efforts to provide measles vaccine have resulted in the control and elimination of the disease in many countries, including substantial reductions in mortality in a number of developing countries where the residual disease burden is greatest. These and other examples provide clear evidence of the power of vaccines in favorably manipulating host immunity to confer dramatic public health benefits, at both the individual and population level.

As vaccines are administered to healthy individuals (often to entire age cohorts or populations), to prevent diseases caused by infectious agents to which they might be exposed in the future, they differ in important ways from pharmacologic agents that are used to treat individuals in whom a disease process is already manifest (or who display predispositions to disease). For this reason, vaccines are unique in the way that they impact on societies and in the way that societal commitment to vaccination determines their ultimate impact. As a result, vaccination efforts provide an informative window on challenges that need to be successfully navigated at the interface between scientific opportunity and societal capacity and commitment. Indeed, current limitations in realizing the full global potential of available vaccines relate more to existing inadequacies in health care financing and infrastructure (especially as they are manifest in developing countries), and the relative value that societies place on disease prevention, than they do to any inherent biological limitations of vaccines themselves. Fortunately, recent acceleration of new vaccine introductions in developing countries through public and private initiatives to build immunization infrastructure and provide funding of vaccine

purchase offers hope that vaccines will one day be equitably available to all who need them.³

The importance of vaccines extends beyond their use as public health tools to include their role as drivers of immunologic discovery. The history of vaccine development is rich with immunologic insights that emerged from careful observations of how diseases spread in populations and how such spread differs in disease-naïve and experienced populations, as well as of how innovative experimental approaches revealed fundamental aspects of immune system function. The general concept of immunity induced by prior exposure to a disease (including its specificity and potential lifelong duration) was appreciated by the ancient Greeks. Use of the word ‘immunity’ itself dates to the 14th century when it was applied to describe the relative susceptibility and resistance of populations to plague. The subsequent successes of Edward Jenner and Louis Pasteur in the development of effective smallpox and fowl cholera immunization strategies, respectively, provided a foundation for modern immunology; Pasteur himself coined the term ‘vaccine’ in recognition of Jenner’s use of vaccinia virus. Jenner’s smallpox immunization studies also provided early experimental support for the concept of immune memory. Pasteur’s efforts provided the first demonstration of the attenuation of pathogens by their propagation in culture (or by passage in nonnatural animal hosts), while Robert Koch demonstrated that killed pathogens could also engender immunity. The discovery of bacterial exotoxins by Emile Roux and Alexandre Yersin facilitated the discovery of antibodies and their potential use in passive immunotherapy with antitoxin antibodies by Emil von Behring and Shibasaburo Kitasato. These discoveries enabled the development of active immunization against diphtheria and tetanus using toxin–antitoxin mixtures. Paul Ehrlich’s development of accurate methods for antibody quantitation made passive immunotherapy and active toxin–antitoxin immunization far more reliable and effective, and provided a stimulus for significant advances in immunologic theory. In each of these instances, vaccine development illuminated central mechanisms of immune system biology.

Vaccine development today has transitioned from an approach that was once largely empirical to one that is based on the hypothesis-driven application of techniques in molecular biology and immunology. Evidence for this synergy can be seen in recent studies of vaccine-elicited immune responses to illuminate primary and memory T- and B-cell responses in

humans, as well as the strong discovery stimulus provided by ongoing efforts to develop new vaccines for major infectious diseases for which vaccines are not currently available.

Vaccine development today faces a number of significant challenges. There exist tremendous public health needs to address major well-known pandemic diseases, including acquired immunodeficiency syndrome (AIDS), tuberculosis, and malaria, for which no vaccines currently exist and for which natural immunity does not provide a helpful guide for vaccine development. Furthermore, there exists a need to confront effectively newly emerging and re-emerging diseases, ranging from the well-known, but constantly changing, threats from influenza pandemics to the appearance of previously unknown zoonotic infections such as the coronavirus that causes severe acute respiratory syndrome (SARS). With changes in population density, mobility, and social constructs, along with alterations in the global climate, ecological circumstances, and the proximity of humans to animal reservoirs for previously confined infectious agents, the concept of new infectious agents entering human populations and spreading rapidly around the world is no longer novel. In confronting prevalent or newly emerging diseases, vaccines are looked to as the most promising line of defense. However, the speed at which new infectious disease threats have been shown to emerge and spread, and the fact that the pathogens that now need to be confronted may display tremendous genetic variability (e.g., human immunodeficiency virus (HIV)) or an identity that cannot be predicted in advance (e.g., avian influenza or agents like SARS) places unprecedented demands on the vaccine development process.

In addition to these new challenges, there remain unmet needs in the derivation of vaccines that can achieve the greatest public health benefit. These needs include the development of new ways to achieve more effective vaccine-elicited immune responses in neonates whose immune systems are immature (or are impacted by maternal antibodies) (Chapter 32) and in the elderly whose immune system function may be waning as a result of immune senescence (Chapter 33). Fortunately, the scientific foundation provided by basic and applied immunology and the use of new methods for pathogen identification, antigen discovery, vaccine production, adjuvant development, and novel vector derivation afford important opportunities for vaccine development and additionally present the possibility of improving on natural immunity.

Success in vaccine development will be predicated on continuing the historical synergy between advances in vaccine technology and basic immunologic discovery. Toward that end, this chapter focuses on preventive vaccines for infectious diseases and how they are developed. Although current routine vaccine recommendations are reviewed, given the active state of new vaccine introduction and evolving vaccine recommendations, as well as differences in recommendations in different countries, readers are encouraged to refer to up-to-date national resources for the most current information. While vaccine approaches are being actively explored to modify beneficially malignant and immunologic diseases (autoimmunity and allergy), these are beyond the scope of the current discussion.

■ IMPACT OF VACCINATION PROGRAMS ■

Unlike other medical interventions, vaccines confer benefits to both individuals and populations.^{4,5} While individuals may be protected from infection or disease by vaccine-induced immune responses, decreasing the number of susceptible hosts in a population also helps break the chain

of transmission that pathogens require to spread and persist in human populations by induction of 'herd immunity.' The benefits of herd immunity depend on achieving sufficiently high immunization rates in a population to impact pathogen transmission dynamics (including the potential for extinction of ongoing interhost transmission). The requisite level of vaccination coverage of a population needed to compromise pathogen spread significantly varies between pathogens, and is influenced both by vaccine efficacy (and its duration) and by the reproductive characteristics and infectiousness of the pathogen.

Analysis of the impact of vaccination programs in the USA provides an example of the beneficial impact of vaccines when used routinely and when high coverage levels are achieved.⁶ As shown in Tables 92.1 and 92.2, vaccination programs in the USA dramatically decreased the annual morbidity of many vaccine-preventable diseases. In many instances, the disease burden from several vaccine-preventable diseases of childhood has been reduced by over 99% since vaccine introduction (e.g., diphtheria, tetanus, measles, mumps, rubella, and polio). The somewhat lower rate of decline of pertussis (the annual morbidity of which has been reduced by a nonetheless impressive 83%) relates to the limited duration of vaccine-induced immunity, which is estimated to wane within 5–10 years after childhood vaccination. It is anticipated that recent availability of pertussis booster vaccines for use in adolescents and adults will lead to significant further declines in pertussis morbidity. Even for diseases targeted by vaccines that have been in widespread use for less time (< 10 years), impressive decreases in disease morbidity have been seen (e.g., varicella, hepatitis A, and pneumococcal disease). In a notable recent demonstration of the population benefits of vaccines, introduction of the 7-valent pneumococcal conjugate vaccine resulted in a decrease of 73% in disease morbidity in children under 5 years of age within the first 5 years of its introduction. Interestingly, the rate of meningitis and bloodstream infections caused by antibiotic-resistant *Streptococcus pneumoniae* also fell by 81% in this age group. In a striking related finding illustrating how vaccines can impact pathogen transmission dynamics, rates of antibiotic-resistant pneumococcal infections also declined by 49% in individuals over the age of 65 who had not received the vaccine. Thus, direct protection by vaccination of children who represent a reservoir of infection provided, via herd immunity, significant indirect benefits to those who did not themselves receive the vaccine.

In addition to their benefits in preventing disease morbidity and mortality, routine vaccination programs are also impressively cost-effective. Evaluation in the USA of the impact of ten vaccines routinely given as part of the childhood immunization schedule (diphtheria, tetanus, pertussis, *Haemophilus influenzae* b (Hib), polio; measles, mumps, rubella, hepatitis B and varicella) found that more than 14 million cases of disease and more than 33 500 deaths were averted over the lifetime of the immunized birth cohort of children.⁷ When the cost of the vaccination program was compared to the economic impact of diseases prevented, these vaccines alone are estimated to save nearly \$10 billion each year. When including indirect economic benefits (such as the time parents take off from work to care for sick children), the annual savings to society exceed \$40 billion. When 30 preventive services were ranked based on clinically preventable disease burden and cost-effectiveness, childhood immunization received the highest score.⁸

Progress in the development of new vaccines accelerated significantly towards the end of the 20th century, with the development of vaccines against diseases that were not previously preventable by vaccination, but also with the development of improved versions of existing vaccines.

Table 92.1 Comparison of 20th-century peak annual morbidity versus current annual morbidity: United States vaccine-preventable diseases

¹Unpublished Centers for Disease Control data, reported November 2006.

Thus, the number of diseases that can be prevented by vaccines included in the US Centers for Disease Control and Prevention's (CDC) routine childhood and adolescent immunization schedules grew from seven in 1985 to 16 in 2007 (Table 92.3 and Fig. 92.1). Moreover, in the past several years, new vaccines have been introduced for adolescents and young adults (e.g., pertussis booster (Tdap), meningococcal conjugate, and human papillomavirus (HPV) vaccines), and older adults (e.g., Tdap and zoster vaccines) have shown that the value of vaccines extends across the human lifespan (Figs 92.1 and 92.2). New combination vaccines have been developed to increase the simplicity and acceptability of vaccination

regimens, as well as to improve overall compliance with the recommended series of vaccines. Such combinations include either those that contain multiple inactivated or recombinant antigens (such as a combination diphtheria, pertussis, tetanus, Hib, and hepatitis B vaccine) or multiple live attenuated viruses (such as a combination measles, mumps, rubella, and varicella vaccine (MMRV)). The development of a combination vaccine is often more complicated than simply combining individual antigens, for when antigens are administered in combination, immunologic interference is sometimes seen. This necessitates titration of antigen combinations (and in the case of combinations of inactivated and/or

recombinant antigens, adjuvant selection) to achieve immune responses that are not inferior to each of the antigens administered individually.

Despite their readily demonstrable public health impact, the value of vaccines is often not appreciated, for when vaccine programs are successful the diseases that they cause become less prevalent and may disappear. However, to prevent resurgence of an infectious disease that has been brought under control, vaccination programs need to be continued. The difficulties facing current efforts to eradicate poliomyelitis have demonstrated that failure to maintain high immunization coverage rates can lead to prompt re-emergence and spread of the disease. Even in developed countries, maintenance of strong immunization programs with high degree of coverage is needed where infectious diseases can travel with remarkable speed – and do so even before the extent of spread is evident.

PRINCIPLES OF IMMUNIZATION

The terms *vaccination* and *immunization* are often used interchangeably. However, vaccination specifically refers to efforts to induce protective immune responses by administration of a vaccine, whereas immunization more generically refers to interventions – either active or passive – that seek to confer immune protection. Active immunization describes the induction of immune responses by administration of a specific antigen or antigens, while passive immunization involves the administration of exogenous immunologically active substances (historically, antibodies present in sera obtained from immune individuals or animals) to confer temporary protection from an infectious pathogen or toxin. Although the approaches for passive immunization waned in the later half of the 20th century, the advent and increasing robustness of monoclonal antibody technology have led to a resurgence of interest in passive immunization.

THERAPEUTIC PRINCIPLES

Special attributes of vaccines

- >> Vaccines benefit both individuals and populations
- >> Vaccines represent one of the most effective and cost-effective public health innovations of all time
- >> To be most effective, vaccines need to be administered to the targeted cohorts of individuals in advance of when they might be exposed to the pathogen of interest
- >> Vaccination of a sufficient number of individuals in a population can, by induction of herd immunity, impact the transmission dynamics of pathogen spread in a population such that even unimmunized individuals are less likely to become infected
- >> With sufficiently high and prolonged immunization coverage, and depending on whether or not nonhuman reservoirs for pathogen persistence exist, it is possible to eradicate infectious diseases from human populations (as was accomplished with smallpox and is now being pursued for poliovirus)
- >> For many contemporary global health threats (e.g., human immunodeficiency virus (HIV), tuberculosis, malaria, and pandemic influenza), the development of effective vaccines is considered to represent the most promising strategy for public health protection
- >> Unlike drugs that are administered to individuals with (or at risk for) specific diseases, vaccines are commonly administered to healthy individuals. As a result, the risk-to-benefit ratio for vaccines requires that vaccines meet high standards of safety and tolerability

Fig. 92.2 continued.

Vaccines seek to engender immune responses similar to those that confer immunity to re-infection in individuals who experience (and survive) natural infection with a given pathogen. In lieu of formal demonstration of a specific type of antibody or cellular immune response that contributes to prevention or accelerated clearance of an infection, most often vaccine efficacy is demonstrated first in the course of a placebo-controlled trial. In some instances, specific immune effector mechanisms, such as a specific level or type of antibody response, can be identified that correlate with immune protection. In this case, the 'correlate of immunity' provides a benchmark against which similar vaccines can be compared.

In the case of most inactivated vaccines, subunit vaccines, and recombinant vaccines that produce antibody responses, but generally meager CD8 T-cell responses, it is likely that humoral immune responses are the primary or sole protective immune mechanism. In the case of live attenuated vaccines that induce both cellular and humoral immune responses against the pathogen, it is likely that both arms of the immune system act in concert to confer immunity. However, the actual mechanisms of immune protection induced by either a natural infection or a vaccine are generally not understood in detail for many infectious diseases.

Similarly, although vaccines depend on the induction of immunologic memory, the magnitude, character, and duration of immune memory differ between vaccines, as can the actual mechanism of immune protection. For certain vaccines, such as those that protect against bacterial diseases induced via production of toxins (e.g., diphtheria or tetanus), protection induced by toxoid-based vaccines is clearly dependent on persistent antibody (IgG) and memory B-cell responses, ensuring that sufficient anti-toxin antibodies are present at the time of toxin exposure to inactivate and clear the toxin. In other cases, such as long-lived protection against hepatitis B, if sufficient levels of antibodies are achieved in the initial immunization period, even hosts who may with time lose detectable levels of antibody responses remain protected.⁹ In this instance, given the relatively long incubation period of hepatitis B, memory antiviral B-cell responses induced by the vaccine can be activated, facilitating neutralization and clearance of the infection before clinical disease is manifest. Although it is popularly believed that vaccines confer protection by inducing 'sterilizing immunity' – wherein an infectious agent is blocked from even infecting one cell in an exposed host – this is clearly not the case for a number of vaccines. For example, the inactivated poliovirus and live attenuated rotavirus vaccines do not prevent some degree of local replication of their pathogenic counterparts in the gastrointestinal tract of exposed hosts. However, they are both effective in preventing clinical disease. In the case of poliovirus vaccine, this is mediated by elicitation of antibody responses that block dissemination of the infection to the central nervous system; while in the case of rotavirus, as yet unidentified immune effectors limit local virus replication so that significant gastrointestinal damage does not occur following infection.^{10,11}

The major types of vaccines licensed for use include live attenuated organisms, killed or inactivated organisms, subunit vaccines consisting of purified (or partially purified) components of an organism, and subunit vaccines produced by recombinant DNA technologies.

LIVE ATTENUATED VACCINES

The use of live attenuated vaccines dates back to the early work of Jenner and Pasteur on smallpox and fowl cholera vaccines, respectively.^{12,13} The fundamental concept of live attenuated vaccines is to mimic the effective

host immune responses that follow natural infections. Most live attenuated vaccines currently in use were derived by propagation of initially pathogenic organisms in culture on cells from different (nonhuman) species, or at nonphysiologic temperatures, for prolonged periods. Driving pathogen evolution in culture to select for variants adapted to growth in heterologous cell types *ex vivo* often leads to the derivation of pathogen variants that grow poorly *in vivo* in humans and are unable to cause clinical symptoms.

Vaccines developed via this approach include those used to prevent a number of viral and bacterial infections, including yellow fever, measles, mumps, rubella, polio (the 'Sabin vaccine'), varicella-zoster (used both for the prevention of chickenpox and shingles) and rotavirus (one version of the available vaccines), tuberculosis, and cholera. More recent technologies being applied to live attenuated vaccine development include the application of reverse genetic strategies (Fig. 92.3) and those involving genetic reassortment with attenuated viral variants, as have been used to develop polyvalent live attenuated vaccines against influenza and rotavirus (Fig. 92.4).^{10,11}

The live attenuated vaccines currently in use are highly efficacious (> 90%) and protection is frequently durable. The efficacy of many live attenuated vaccines likely reflects the ability of the attenuated vaccine to replicate within vaccinated hosts, and to expose the immune system to pathogen-derived antigens in a manner that closely resembles the nature, location, and effects of natural infection. Because live attenuated vaccines replicate within immunized individuals, they can induce both cellular (CD4 and CD8) and humoral (B-cell) effector responses and immunologic memory. In addition, as the live attenuated vaccines likely activate the host innate system in a manner similar to their pathogenic parents, they provide inherent adjuvant effects in augmenting adaptive immune responses.

A key consideration in the development of any live attenuated vaccine relates to the relative balance between the ability to induce sufficient immune responses *in vivo* to confer protection (often associated with level of preserved replicative ability *in vivo*), and the ability to cause symptoms (which may also relate to the extent of *in vivo* replication). As such, an effective but also safe and well-tolerated vaccine needs to strike a specific balance between level of attenuation and level of immunogenicity. In addition, depending on the nature and number of genetic mutations responsible for the attenuated phenotype, a potential risk of reversion to a pathogenic form exists for certain vaccines. For most live attenuated vaccines, this has not been observed to be a problem in clinical practice – likely because the attenuating mutations are sufficiently numerous or genetically stable. One vaccine where reversion to pathogenic form was seen involved specific components of the live attenuated oral poliovirus vaccine (OPV; the 'Sabin vaccine'). In this instance, vaccine reversion to wild-type was shown to lead rarely to cases of paralytic polio (approximately one case per million doses administered).¹⁴ Based on these observations and the elimination of endogenous polio transmission in many developed countries, the inactivated polio vaccine (IPV; the 'Salk vaccine') was substituted for OPV. However, in light of a favorable cost–benefit ratio, high degree of efficacy, and ease of administration, OPV continues to be the mainstay of polio vaccination efforts in developing countries.

KILLED OR INACTIVATED ORGANISMS

The use of physical or chemical methods to kill or otherwise inactivate a pathogenic organism represents a second major approach to vaccine production.^{15,16} In most cases, treatment with chemical agents such as β -propiolactone and formaldehyde is used to eliminate pathogen

Fig. 92.3 New vaccine strategies: reverse genetic approaches. The term ‘reverse genetics’ refers to the use of recombinant DNA methods to generate infectious viruses possessing genomes derived from cloned cDNAs. Such cDNAs can be modified to study the impact of specific genetic modifications to viral phenotype, providing a new approach for the generation of live attenuated vaccines via either introduction of targeted mutations or, in the case of segmented viruses, the preparation of vaccines via genetic reassortment (see Fig. 92.4). Reverse genetic methods provide promising tools for the study and defined manipulation of both nonsegmented and segmented negative-strand RNA viruses (such as the respiratory syncytial virus (RSV) and influenza viruses, respectively). The use of reverse genetic strategies to generate infectious viral progeny from cloned cDNAs is shown above. Influenza virus genomes are comprised of eight single-stranded (negative-sense) RNA segments. Initiation of influenza virus RNA (vRNA) transcription from negative-sense genomic RNAs, and the replication of the virus genome, depends on the viral ribonucleoprotein (RNP) complex (which includes viral RNA, the nucleoprotein (NP) and three polymerase proteins (PB1, PB2, and PA)). To generate infectious influenza virus from cDNAs of the vRNA genome segments, cells are cotransfected with all eight segments of vRNA under the control of RNA polymerase promoters. Cellular polymerase I (pol 1) synthesizes vRNAs that are then replicated and transcribed by the viral polymerase and NP proteins that comprise the RNP complex. Reverse genetics strategies are expected to facilitate the generation of novel flu vaccines by enabling preparation of well-defined vaccine preparations comprised of donor ‘backbone’ viral segments (see Fig. 92.4) that harbor specific attenuating mutations with vRNA segments encoding the hemagglutinin (HA) and neuraminidase (NA) proteins obtained via reverse transcription of vRNA genes from circulating viruses (including those prepared from pandemic strains that may be difficult and/or unsafe to propagate in large manufacturing scale). (Adapted from Marsh GA, Tannock GA. The role of reverse genetics in the development of vaccines against respiratory diseases. *Exp Opin Biol Ther* 2005; 5: 369–380, with permission from Expert Opinion.)

infectivity. While this approach has the benefit of presenting most of a pathogen’s antigenic repertoire to the immune system of the immunized host, it can only be used in instances where the inactivated pathogen does not possess constituents that would confer significant toxicity. Vaccines based on killed pathogens are believed to exert their protective effects via elicitation of pathogen-neutralizing antibodies and the induction of memory B-cell responses (likely in concert with CD4 T-cell memory). However, because inactivated pathogens cannot accomplish *de novo* synthesis of pathogen-derived gene products in antigen-presenting cells (APCs), they do not typically induce CD8 T-cell responses (Chapter 6). In addition, killed vaccines are generally less immunogenic than live attenuated vaccines. As a result, they are commonly administered with an adjuvant (most often alum: see section on Adjuvants, below) to augment their immunogenicity. A number of viral and bacterial vaccines currently in use are killed/inactivated vaccines, including whole-cell *Bordetella pertussis* vaccine and the influenza virus, rabies virus, and hepatitis A virus vaccines.

PURIFIED SUBUNIT VACCINES

A number of bacteria produce toxins that represent the major pathogenic components responsible for disease in infected humans. Examples include *Corynebacterium diphtheriae* and *Clostridium tetani*. Detoxified versions of these toxins are referred to as ‘toxoids,’ and represent the purified components of vaccines preventing diphtheria and tetanus, respectively. Toxoids have historically been produced by chemical inactivation of toxins, but more recently, genetic inactivation via targeted mutagenesis has been employed. The acellular pertussis vaccine is also a purified subunit vaccine composed of a defined set of protein constituents prepared from cultured *Bordetella pertussis*. The mechanism of immune protection conferred by purified subunit vaccines is the antibody response elicited by vaccination.

Antibodies directed against the capsular polysaccharides present on encapsulated bacteria also confer protective immunity in a number of important instances by inducing antibodies that exert opsonophagocytic

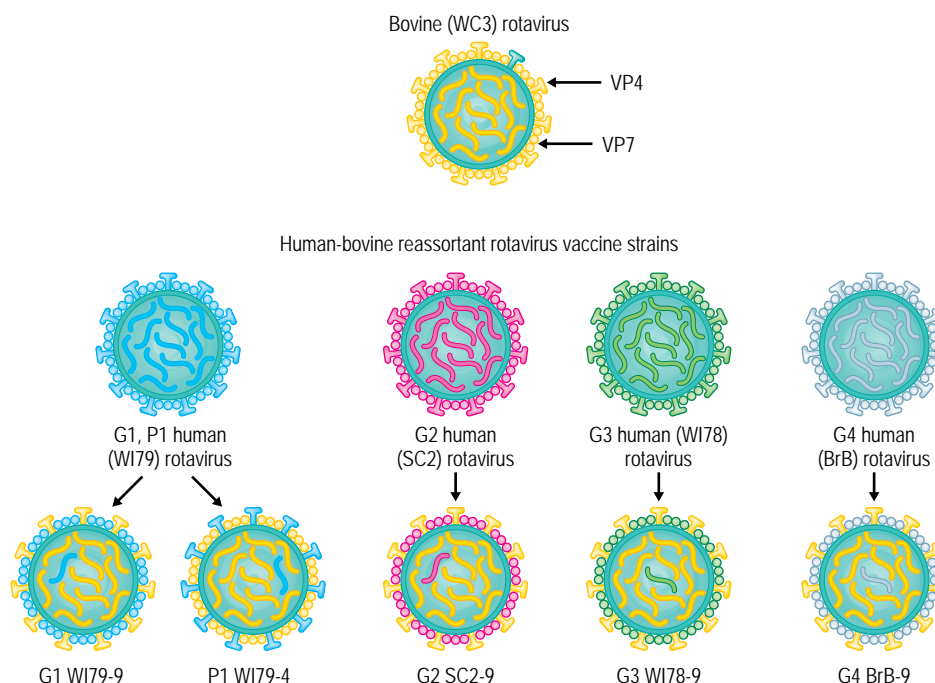

Fig. 92.4 New vaccine strategies: genetic reassortment approaches. Viruses with segmented genomes provide a new approach for the generation of attenuated vaccines via Mendelian genetic reassortment. If two such segmented viruses with different genetic characteristics are used to infect one cell, the progeny viruses from this mixed infection will carry a range of mixtures of the genes of the two parent viruses. Using either genetic or immunologic screening methods, reassorted viruses carrying the precise gene composition of interest can be selected. This approach has recently been employed to generate live attenuated vaccines against rotavirus and influenza virus. The strategy for generation of the pentavalent bovine–human reassortment rotavirus vaccine is shown above. Rotaviruses have a segmented double-stranded RNA genome comprising 11 independent RNA elements. The outer shell of the virus comprises two proteins VP4 and VP7 that are involved in cell binding and entry and that specify the viral serotype (P type for VP4 and G type for VP7). VP4 and VP7 also represent the targets of virus-neutralizing antibodies. The pentavalent bovine–human rotavirus vaccine was generated by a ‘modified Jennerian’ approach in which the bovine rotavirus WC3 (which is attenuated in humans as a result of host range restriction) serves as the gene donor for the backbone on to which gene segments encoding four common human rotavirus G types (G1–4) as well as one very common P type (P8) (derived from individual rotavirus isolates) were reassorted via a process of cell co-infection and subsequent selection of the recombinant viruses with the desired composition of bovine and human gene segments. An analogous genetic reassortment approach has also been used to generate live attenuated influenza vaccines. In this instance, three attenuated ‘cold-adapted’ viral strains (two A types and one type B) are used in co-infections in tissue culture with recent circulating wild-type influenza strains to derive vaccine strains that include the two relevant hemagglutinin (HA) and neuraminidase (NA)-encoding gene segments admixed with the six ‘backbone’ genes from the attenuated master donor virus for use in annual influenza vaccines.

effects (promoting phagocytosis of antibody-coated bacteria) and, in some instances, bactericidal effects.¹⁷ Initial successful vaccine efforts against *Streptococcus pneumoniae* and *Neisseria meningitidis* utilized purified preparations of capsular polysaccharides. Although such purified polysaccharides can induce protective levels of antibody responses in adults, they are poorly immunogenic in children under 2 years of age (as a function of the relative immaturity of their immune systems). In addition, T-Independent antibody responses elicited by purified capsular polysaccharides are less durable than those that are produced in the presence of CD4 T-cell help. As a means of both augmenting antibody responses against polysaccharide antigens in young children and facilitating their persistence, the development of conjugate vaccines represented an important advance.¹⁸ In this approach, purified polysaccharides are chemically conjugated to a carrier protein (such as diphtheria toxoid or an outer-membrane protein complex (OMPC) derived from *N. meningitidis*). The carrier protein augments CD4 T-cell

helper responses to the polysaccharide antigens, and enables elicitation of durable protective antibody responses even in young children. Polysaccharide-conjugate vaccines have been produced that protect against *Haemophilus influenzae* b, *Streptococcus pneumoniae*, and *N. meningitidis* infections.

RECOMBINANT PROTEIN SUBUNIT VACCINES

The advent of recombinant DNA technologies provided a transformational event in the history of vaccine development. In addition to facilitating the identification and expression of pathogen-derived protective antigens, techniques were developed that enabled their large-scale manufacture as vaccines. Recombinant DNA technologies provided a new path to develop vaccines against pathogens, such as hepatitis B virus (HBV) or HPV, that could not be grown in culture. In addition, recombinant methods provided the potential to derive even safer versions of available vaccines.

Fig. 92.5 New vaccine strategies: recombinant virus-like particle (VLP) approaches. In specific instances, VLPs can be produced via a process of self-assembly of individual viral capsid proteins produced by recombinant DNA methods in cell culture systems. This approach has a number of attractive aspects, including the ability to produce VLPs that accurately display conformationally correct epitopes recognized by neutralizing antibodies and the absence of pathogen-derived nucleic acids. In addition, recombinant VLPs have been employed to derive safe and effective vaccines for pathogens, such as hepatitis B virus (HBV) and human papillomavirus (HPV), that cannot be grown in culture (and are thus refractory to standard vaccine approaches of attenuation or inactivation). The generation of the VLPs that comprises newly developed HPV vaccines is shown. The HPV L1 proteins (which represent the major capsid protein and target of virus-neutralizing, protective antibodies), derived from HPV types of interest (e.g., types 16, 18, 6, and 11) are produced via recombinant methods. Under appropriate conditions, individual bioengineered L1 proteins first self-assemble into pentamers, and then into VLPs that are comprised of 72 pentamers and that are almost identical, both morphologically and antigenically, to infectious HPV virus particles. VLPs prepared from individual HPV types are then combined with specific adjuvants to prepare the final vaccine products.

The first recombinant vaccine developed, the recombinant hepatitis B surface antigen (HBsAg) prepared in yeast, was developed in hopes of avoiding safety concerns related to the plasma-derived HBsAg vaccine.¹⁹ The knowledge that immune sera could provide protection by passive immunization of naïve hosts, and that purified inactivated plasma-derived HBsAg vaccine could elicit protective antibodies, laid the groundwork for development of this recombinant vaccine.²⁰ The recombinant vaccine, when combined with adjuvant (alum), elicits favorable immune responses, is highly efficacious and is well tolerated – all features that recombinant vaccines are now expected to deliver. The second recombinant vaccine developed targeted prevention of *Borrelia burgdorferi* infection (the cause of Lyme disease), and was based on a purified recombinant version of the OspA protein. This vaccine, although conferring some degree of efficacy, faced implementation challenges, and was not widely embraced. As a result, it was withdrawn from the market.

More recently, recombinant technology-derived purified subunit vaccines have been developed that consist of virus-like particles (VLPs) that self-assemble when the L1 protein of HPV is produced in isolation of other viral proteins (Fig. 92.5).²¹ The L1 protein is the target of virus-neutralizing antibodies and vaccines consisting of a mixture of types 16 and 18 (the cause of ~70% of cases of cervical cancer) and 6 and 11 (the cause of ~90% of cases of genital warts) or of HPV types 16 and 18 alone have been shown to be highly efficacious and well tolerated.²² Interestingly, HPV VLPs induce antibody responses that exceed those that follow natural HPV infections.²³

In light of these successes, and the power and versatility of recombinant antigen production methods, a major proportion of new vaccine development efforts involves the use of protein subunit vaccines produced by recombinant technologies. Vaccines produced by this method

are those that depend largely or exclusively on the induction of antibodies against individual or a selected subset of pathogen proteins. Because a number of proteins produced in isolation by recombinant methods have been observed to elicit lower immune responses than do natural infections or live attenuated vaccines, the development and use of adjuvants to optimize recombinant vaccine immunogenicity represent an important parallel area for future exploration.

VACCINE DEVELOPMENT AND EVALUATION

As a necessary prelude to clinical evaluation of candidate vaccines in humans, extensive preclinical research and development activities are undertaken to establish that the vaccine candidate has the desired properties. Toward this end, a number of key issues need to be addressed. First, animal studies must show that the vaccine candidate raises the desired type and magnitude of immune response against the infectious agent. Second, the vaccine needs to protect animals against death or disease in an appropriate challenge model, when feasible. Ideally, in the course of these studies, a specific type or level of immune response, referred to as a correlate of immune protection, can be identified. Third, the vaccine should be relatively free of serious discernible toxicities and side effects in animals when administered by the route intended for humans. Fourth, it is necessary to demonstrate that the vaccine can be produced in a consistent manner by a process that is consistent with the current good manufacturing practices (cGMP) process by which the first clinical trial materials will be produced (www.fda.gov/cber/gdlns/indcgm.pdf).

KEY CONCEPTS

CONSIDERATIONS GUIDING VACCINE DEVELOPMENT

The development of new vaccines depends on the convergence of public health need, biological plausibility, and practical feasibility. Vaccine development programs are influenced by multiple considerations, including:

- >> What are the major unmet medical and public health needs today?
- >> What is known about the natural history and pathogenic mechanisms of the infection of interest?
- >> Is immunity to a given antigen associated with protection against disease following re-exposure in the context of natural infection?
- >> If natural immunity capable of preventing re-infection follows an initial infection with the pathogen, can a specific host immune effector mechanism (e.g., antibody, CD8 T-cell) be identified as the likely agent (or 'correlate') of immune protection? If so, can a threshold level of this specific immune correlate needed for protection from re-infection be defined?
- >> Can the pathogen be grown in culture? If so, does the pathogen cause such a life-threatening disease that an attenuated version of the virus would face an impossible barrier for demonstration of safety?
- >> Can a specific antigen (or antigens) be identified that represents the target of protective host immune responses?
- >> If the protective immune response is mediated by antibodies, can the target antigen (be it a protein or polysaccharide) be produced in scalable quantities in a form that mimics its native structure so that it can effectively elicit antibody responses that can block the key functional role(s) of the target molecule in the pathogen lifecycle or otherwise lead to the clearance of an incipient pathogen infection?
- >> Having chosen an antigen and presentation system, what is the best way to produce it on a large scale? Choices will be limited by the nature of the antigen and delivery system, but definition of an optimal system for producing the vaccine (prokaryotes like *Escherichia coli*, or diverse eukaryotic hosts including yeast, insect cells, plants, or cultured plant cells, mammalian cells) is a central consideration.
- >> What is the most effective way to present the antigens of the pathogen of interest to the immune system? Modern molecular biology and biochemistry have provided numerous options for vaccine immunogen presentation, including recombinant proteins (and recombinant virus-like particles (VLPs)), synthetic proteins, protein-polysaccharide conjugates, and gene delivery systems (recombinant viral vectors, or DNA vaccines)
- >> Is the antigen of interest sufficiently immunogenic on its own, or is augmentation of the desired immune response by conjugation to a specific carrier or addition of an adjuvant necessary to elicit a sufficient and sufficiently durable immune response in individuals in the target population for vaccination?

- >> What types of potential safety concerns can be anticipated for the vaccine in question?
- >> What is the attack rate of the infection in the general population? If the infection occurs relatively rarely in an overall population, can a subset of the population be identified that has a higher risk of infection so as to accelerate the achievement of statistically significant protection? Is this subset sufficiently similar to the rest of the population to enable extrapolation of the clinical results to the broader target population as a whole?
- >> What tests to evaluate vaccine immunogenicity will need to be carried out on clinical samples obtained from participants in the clinical trials? Will measurement of antibody titers, T-cell responses, pathogen presence and quantity, pathogen serotype, and any other parameter peculiar to the disease in question represent the primary criteria for vaccine effect? Development and validation of these tests represent an essential component for the feasibility and success of a vaccine clinical study

Even before preclinical studies are completed, vaccine developers typically begin an initial dialog with regulatory authorities (such as the Food and Drug Administration (FDA) or the European Medicines Agency (EMA)) to set expectations about what will be necessary and sufficient for advancement to clinical studies in humans (www.fda.gov/cber/genetherapy/isct092506sh.pdf).

Phase I studies primarily focus on detailed assessment of the safety and tolerability of a vaccine, but evaluation of its immunogenicity is also frequently conducted. Generally, a phase I study includes fewer than 100 healthy volunteers divided unequally between those who receive vaccine or placebo (2 or 3 vaccinees per placebo recipient). Phase I studies typically employ escalating doses of the candidate vaccine, with a dose range progressively increasing in steps of three- to fivefold often being used. Blood samples are taken at prescribed intervals and analyzed for laboratory evidence of potential toxicity, as well as for evidence of vaccine-elicited immune responses. A phase I study is considered successful if it demonstrates that the candidate vaccine is well tolerated or identifies any immediate safety concerns that will need to be closely monitored in potential future clinical studies. Ideally, phase I studies also provide an initial indication of the optimal dose level and number of doses required.

A phase II study typically includes several hundred to a few thousand volunteers (randomized between vaccine and placebo) and can assume two general design types. Phase IIa studies provide additional safety data on a larger number of individuals of the intended age who receive the intended vaccine dose (who are more representative of the general population intended for vaccine use than the very healthy individuals included in the phase I study), as well as provide additional data on vaccine immunogenicity. Even larger phase IIb studies can provide additional data on vaccine safety and immunogenicity in subjects generally representative of those for whom the vaccine might be recommended, but importantly, also provide the first opportunity to address to answer the question, 'Does this vaccine work in humans?' The size of a phase IIb study needed to detect a signal of vaccine efficacy depends on the attack rate of the infection being targeted by the vaccine.

Phase II studies also present the first opportunity to identify a potential laboratory immunological correlate of protection from disease – if nature and prior experience have not already done so. In order to do so, the placebo recipients in the phase II trial must experience a sufficient number of cases of disease while vaccine recipients need to exhibit significant evidence of decreased risk of infection or disease. In addition, immunological measurements in the vaccinees need to capture the relevant protective immune responses (e.g., the type and level of antibody and/or cellular immune response that predict protection) and measure them with sufficient precision and reliability. If laboratory measurements of immunity correlate with vaccine protection, subsequent refinements of the vaccine, its adjuvant, its manufacturing process, or its regimen may be assessed by simple immunogenicity studies, rather than repeating efficacy studies. Once efficacy is established for a vaccine, it is very difficult to carry out a double-blinded, placebo-controlled efficacy study.

Vaccines that have been shown to be immunogenic and well tolerated in phase II studies can then advance to pivotal phase III studies required for vaccine licensure by regulatory authorities. Phase III studies are intended to expand further the safety database in a larger number of individuals (who are representative of the specific populations for which the vaccine will ultimately be used), establish definitive evidence of protective efficacy, and to establish clinical consistency of the vaccine made by the process run in the facility intended for licensure and commercialization (www.fda.gov/cber/genetherapy/isc092506jcr.htm). Typically, phase III studies include 10 000 or more subjects in a blinded, placebo-controlled design. This size trial allows the identification of less frequent safety events. It also provides an opportunity to capture data on health care utilization, cost, and impact of the vaccine on these parameters. As a new vaccine will ultimately be included in a vaccine program where multiple vaccines may be administered at the same time, it is also necessary to conduct concomitant-use studies. The developer of the new vaccine must show that the new vaccine does not impact on the immunogenicity of the existing vaccines, and that the existing vaccines do not impact on the immunogenicity of the new vaccine.

■ LICENSURE AND RECOMMENDATION OF VACCINES ■

In contrast to drugs, where licensure by the FDA is the primary determinant of how a new product is implemented in medical practice, vaccine use in the USA includes an additional process that evaluates how best to employ a new vaccine to optimize its implementation and public health impact. The US CDC has responsibility for making recommendations about the use of licensed vaccines, and it relies on its Advisory Committee on Immunization Practices (ACIP) for guidance. The ACIP considers several aspects in addition to a vaccine's safety and efficacy, including the anticipated cost-effectiveness and practical feasibility of potential alternative vaccine deployment strategies and consideration of how a new vaccine may be successfully implemented in clinical practice to achieve the greatest public health impact. Once the CDC has received, reviewed, and accepted the recommendation of the ACIP, the recommendation is published in its final official form in *Morbidity and Mortality Weekly Report* (MMWR; www.cdc.gov/nip/publications/acip-list.htm).

■ VACCINES FOR ROUTINE USE AND IN SPECIAL POPULATIONS ■

The recommended immunization schedule for children and adolescents (Fig. 92.1) is updated on an annual basis and can be accessed at www.cdc.gov/nip/recs/child-schedule.htm. The recommended adult immunization schedule (Fig. 92.2) is also updated on an annual basis and can be accessed at www.cdc.gov/nip/recs/adult-schedule.htm. The recommended adult immunization schedule includes information concerning use in special populations (such as health care workers and pregnant women) and individuals with specific conditions associated with altered or impaired immune function (such as individuals with congenital and acquired immunodeficiency syndromes, recipients of immunosuppressive therapies, malignancies, asplenia, liver disease, and renal disease). Readers are encouraged to check to ensure that they are following current recommendations.

Pregnancy registries currently exist for four vaccines in the USA. Health care professionals are encouraged to report exposures of pregnant women to the appropriate registry: HBV vaccine (800-670-6126), HPV vaccine (800-986-8999), meningococcal vaccine (800-822-2463), and varicella vaccine (800-986-8999).

■ VACCINE SAFETY ■

Unlike drugs that are utilized to treat individuals suffering from a given disease state, vaccines are administered to normal, healthy infants, adolescents, and adults. Consequently, standards for the safety and tolerability of vaccines are set at a very high level. When developing a new vaccine, a graded process of clinical studies is employed that involves increasingly larger numbers of volunteers and that typically progresses from individuals who are selected to be free of any identifiable health problems to those who are selected to be representative of the overall population for whom the vaccine is being developed. If phase I studies reveal no evidence of safety concerns and the desired evidence of immunogenicity, a major focus of the series of larger randomized double-blind, phase II placebo-controlled studies that are then conducted is to explore the safety and tolerability of a vaccine in increasingly vulnerable populations (such as those who may have identified pre-existing health problems or asymptomatic abnormalities detected on screening laboratory studies).

Reflecting the importance of documenting the safety of a new vaccine, phase III studies to assess the safety and efficacy of a new vaccine now typically involve large numbers of volunteers. Indeed, as a result of needing to provide evidence for safety, it is now common to have the size of the phase III trial be significantly larger than would be necessary to document vaccine efficacy. The ability of a study to identify an increased risk of any given adverse event with sufficient statistical power is directly related to the size of the population in the study. As a general rule, a study of 300–400 subjects is needed to measure the risk of an event that happens in one out of 100 individuals. For one in 1000, 3000–4000 subjects are needed. Even in studies of this size, very rare events may not be identified, and if a specific safety concern exists substantially larger trials may be needed.

The recent experience with the development of rotavirus vaccines provides an illustrative example of the importance placed on documenting vaccine safety.²⁴ Rotavirus is an important cause of serious gastroenteritis

in infants and young children, and the associated diarrhea and vomiting can lead to life-threatening dehydration. In developing countries where health care resources and effective rehydration options are limited, over 600 000 infants die of rotavirus gastroenteritis each year.²⁵ Given the global importance of rotavirus gastroenteritis, the first licensure of an orally administered rotavirus vaccine in 1998 was a very welcome advance. However, as the vaccine entered routine pediatric practice, it was recognized that a low, but increased incidence of intestinal intussusception was seen after the first and second doses (with about one case of intussusception seen per 10 000 vaccinees).²⁶ Upon recognition of this association, the vaccine was withdrawn from the market.²⁷

With the evident public health need for a safe and effective rotavirus vaccine, it was hoped that alternative rotavirus vaccines then in development (both oral vaccines based either on a combination of bovine–human reassortant viruses (Fig. 92.4) or an attenuated human rotavirus strain) might differ from the first licensed rotavirus vaccine and not result in an increased rate of intussusception. However, to demonstrate that these alternative rotavirus vaccines were safe, and that an increased risk of intussusception was not inherent to rotavirus vaccines as a class, very large-scale safety studies were required. Toward this end, the safety of each of these vaccines was evaluated in studies involving about 70 000 infants – just to evaluate whether the rate of intussusception in vaccinees was discernibly increased compared to the normal background rates seen in the placebo recipients.^{10,11} Fortunately, both vaccines were found to be well tolerated and no increase in intussusception was observed in vaccine as compared to placebo recipients. In light of the documented efficacy of these vaccines determined in earlier and significantly smaller phase III trials, both have now been licensed in a number of countries. However, even with the large phase III studies conducted for these newer rotavirus vaccines, they will still be studied in large postlicensure active surveillance safety studies and closely monitored in active and passive vaccine safety surveillance systems (see below).

Following vaccine licensure, safety is tracked via a number of means, including both active and passive surveillance studies of adverse events. Active surveillance includes phase IV postmarketing studies of vaccine safety in larger populations in real-world use. Formal postmarketing studies can include tens of thousands of individuals or more.

An alternative type of postmarketing safety study is carried out by the US FDA and the CDC within the context of the Vaccine Adverse Event Reporting System (VAERS) database (www.vaers.hhs.gov) or by telephone: 800-822-7967). The VAERS database accepts spontaneous reports of adverse experiences from health care providers, patients, parents, vaccine manufacturers, and other sources.²⁸ The best use of the VAERS database is to identify signals in a population that may appear following the introduction of a new vaccine.

A newer vaccine safety surveillance system, known as the Vaccine Safety Database (VSD), has been developed by the CDC in cooperation with seven large health maintenance organizations (HMOs) around the USA.²⁹ The VSD contains the complete medical records of all the members from the participating HMOs, and the information used to populate the database is entered by health care professionals using relatively consistent terminology, improving the quality, uniformity, and usefulness of the data. Particularly important is that the VSD construct allows comprehensive epidemiological analyses to determine if the incidence rate of a specific adverse event is higher among vaccinees than nonvaccinees. In addition to VAERS and the VSD, the CDC has also created a Clinical

Immunization Safety Assessment Network that reviews patterns of clinical syndromes that may follow vaccination.

While the safety profile of a vaccine can be relatively well defined through the efforts described above, confidence in vaccination programs has often been challenged by public perceptions, either real or unsubstantiated, about vaccine safety. In some instances, specific vaccines have been associated with increased incidence of a specific adverse experience, such as the association between the first-generation rotavirus vaccine and an increased risk of intussusception following vaccination. However, a number of other safety concerns that have emerged are not supported by scientific evidence. An example of this can be found in the case of concerns about the association of whole-cell pertussis vaccines with permanent brain damage – concerns that were later shown to be unfounded. Nevertheless, public concerns about the safety of the whole-cell pertussis vaccine resulted in decreased levels of pertussis vaccination coverage that were soon followed by epidemics of whooping cough in the UK and Japan.³⁰ Another example is the allegation that certain vaccines, such as the combination measles, mumps, rubella (MMR) vaccine, are associated with autism. Highlighting how perceptions of temporal association can give rise to public concerns, MMR vaccines are generally given around 1 year of age, and autism is generally diagnosed in the second year of life. Although the alleged causal association between MMR and autism has been refuted by thorough scientific analyses, reports in the popular media in the UK resulted in a dramatic drop in vaccination rates, followed by an increased rate of new infections.^{31,32}

■ VACCINES NOT YET AVAILABLE ■

Although an impressive armamentarium of vaccines is now available, safe and effective vaccines have yet to be developed for a number of very important infectious diseases. The reasons underlying the lack of effective vaccines for an array of important pathogens include biological considerations, safety concerns, and practical constraints. Of these, the biological considerations are often the most important barrier. As discussed above, vaccines have been successfully developed for pathogens whose natural infections give rise to natural immunity wherein the infected host (at least those who survive initial infection) is no longer susceptible to re-infection (such as measles, yellow fever virus, or smallpox) or who experiences significantly less severe clinical sequelae upon re-infection (such as rotavirus). In instances where natural immunity follows natural infection, not only is a precedent for immune protection established, but the nature of protective host responses can be studied, providing a correlate of protection to guide vaccine development efforts. However, for many of the pathogens for which vaccines remain elusive, natural immunity does not follow natural infection. In the absence of natural immunity, not only is a precedent for successful immune containment lacking, but no potential correlates of protection are available to inform vaccine development. In some instances where natural immunity does not follow natural infection, persistent infections are established and maintained by active virus replication that cannot be controlled or cleared by host immune responses (such as HIV and hepatitis C).

Alternatively, other pathogens are able to persist in the host through establishment, via diverse mechanisms, of latent infections that are resistant to host immune clearance (such as tuberculosis or herpes viruses (such as herpes simplex virus (HSV) or Epstein–Barr virus (EBV))). In other instances, even when the host is cleared of an infection via drug

treatment, the host remains susceptible to re-infection and disease in the future (such as malaria). Although different pathogens have evolved diverse strategies for evasion of host immune responses – ranging from manifestation of tremendous genetic diversity and propensity for immune escape; to sequestration of critical structural domains that might be susceptible to antibody neutralization; to the utilization of specific mechanisms to evade host innate and adaptive immune effectors – the common end result is frustration of vaccine development.

While failure of host clearance of an infection is a common theme underlying the lack of vaccines, additional obstacles to vaccine development include other immunologically related considerations as well as both practical and safety considerations. Examples of immunologically related obstacles include instances where prior exposure to a given pathogen predisposes the host to more severe disease manifestations upon re-infection (as has been proposed in the case of dengue virus) or where earlier vaccine development efforts inadvertently lead to severe adverse events following infection with the targeted pathogen (such as respiratory syncytial virus (RSV)). In each of these cases, the adverse events that follow a secondary immune exposure are believed to be the result of immunopathologic responses that result from the nature of the immune response elicited by the initial exposure to pathogen-derived antigens (by either infection or vaccination). Given that the mechanisms underlying these immunopathologic processes are incompletely understood, the development of vaccines that are highly immunogenic but not similarly inclined to elicit immune-mediated adverse consequences represents a substantial challenge (especially given the very high expectations for vaccine safety). An additional immunologically related challenge relates to the observation that certain organisms encode antigens that resemble constituents of the human host. For example, in the case of *Neisseria meningitidis* group B, the bacterial polysaccharide resembles those found on certain human cell lineages, thus raising concerns about whether polysaccharide-based vaccines successfully developed for group B *N. meningitidis* might yield undesirable autoimmune responses.³³

An additional distinct, but important, practical barrier to new vaccine development relates to the prevention of diseases that are threats to pregnant women or their offspring (where immunization of the pregnant woman might be able to protect the neonate). Although a number of inactivated vaccines are either routinely recommended for use in pregnant women (e.g., inactivated influenza vaccine) or can be used in pregnant women for pre- or postexposure prophylaxis for those at risk of infection (e.g., inactivated hepatitis A vaccine and recombinant HBsAg vaccine), the development of new vaccines specifically for use in pregnant women or the study of new vaccines in pregnant women has been impeded by concerns arising from potential litigation that might follow the appearance of a congenital abnormality in a child born to a mother who was vaccinated while pregnant.³⁴ Given the 2–3% prevalence of congenital abnormalities, the practical difficulties in proving the safety of a new vaccine specifically administered to pregnant women, and the current litigious environment surrounding vaccines, the development of new vaccines to address important infections of pregnant women and their neonates (e.g., group B streptococcus: GBS) faces significant challenges.

There remain a number of important infectious diseases for which no effective preventive vaccines exist. Below, we list the major ‘missing’ vaccines, comment on why they are not yet available, and highlight the major approaches currently being explored to develop them.

HUMAN IMMUNODEFICIENCY VIRUS (CHAPTER 37)

At the end of 2006, an estimated 40 million people were living with HIV infection, and in the preceding year approximately 4.5 million people became newly infected, and approximately 3 million individuals died of AIDS. As the most promising biomedical intervention to contain the AIDS pandemic, the development of an HIV vaccine is a top global health priority. Yet, HIV infection represents a vexing challenge to vaccine development.^{35,36} HIV infection does not result in clearance of the virus due to a host immune response. Following infection of target cells, the genome of HIV – a retrovirus – is transcribed into a DNA copy via the action of reverse transcriptase. The newly formed DNA copy of the HIV genome then integrates into the host cell chromosomes (referred to as a provirus) as a requisite step in the viral lifecycle. Once integrated into the chromosome of an infected cell, the HIV provirus can alternatively be actively transcribed, leading to the synthesis of viral mRNAs and subsequently to production of new virus particles, or it can remain in a transcriptionally silent, functionally latent state in a small percentage of infected cells. As infected cells harboring latent HIV proviruses do not produce HIV protein antigens, they cannot be recognized by host antiviral immune responses and can thereby persist undetected. Upon subsequent activation of latently infected cells at some later time, viral RNA transcription can be coincidentally activated leading to production of progeny virions.

As HIV targets activated CD4 T cells for infection and consequent depletion, the host's ability to mount both HIV-specific and non-HIV-specific immune responses is progressively impaired. The ability of the host to clear HIV infection is further complicated by the extensive genetic diversity of virus populations that emerge, and progressively diverge, within infected individuals as a function of a replicative cycle that is accomplished by the inherently error-prone reverse transcriptase and the numerous cycles of replication that occur in infected individuals. As a result of these influences, genetically diverse populations of HIV variants are established in infected persons that facilitate the outgrowth of genetic variants that can escape from selective pressures – be they effective host cellular or humoral immune responses, or the inhibitory effects of antiretroviral drugs.³⁷ An extraordinary degree of genetic diversity is also manifest in the HIV variants seen in different individuals and in different geographic regions. As successful vaccines for other infectious agents have historically had to protect against pathogens exhibiting only limited genetic diversity, HIV represents an unprecedented challenge.

As many successful vaccines protecting against viral infections are predicated on the induction of neutralizing antibody responses against the viral surface proteins that mediate attachment to and entry into target cells, significant efforts have focused on the potential of the HIV surface envelope (Env) glycoprotein, Gp120, to elicit infection-neutralizing antibodies.³⁸ Unfortunately, HIV gp120 is highly resistant to the action of antibodies by virtue of its heavy glycosylation and its native conformation that shields functionally critical structural domains from antibody binding. As a result, candidate gp120-based vaccines have failed to elicit meaningful levels of neutralizing antibodies in immunized human volunteers and have not protected from HIV infection in two large phase III studies.

Given the inability, to date, of candidate HIV Env-based vaccines to elicit appreciable levels of neutralizing antibodies, current vaccine strategies are largely focused on the induction of CD8 cytotoxic T-cell responses against the more constrained and conserved antigens, such as

gag, *pol*, and *nef*. It has been hypothesized that induction of high levels of HIV-specific CD8 T-cell responses prior to infection may not prevent infection, but may enable infected individuals to control virus replication better. Should this hypothesis be valid, individuals immunized with such vaccines may exhibit lower levels of ongoing HIV replication, progress to AIDS more slowly, and potentially be less likely to transmit HIV infection to others. Much of this work involves vectored gene delivery systems (such as adenoviral vectors, described below). However, the recently announced results of a phase IIb 'test of concept study'³⁹ failed to demonstrate a beneficial effect on either prevention of infection or reduction of viral load among volunteers who received the vaccine despite the induction of appreciable levels of HIV-specific CTL responses by the recombinant adenovirus-based vaccine employed. While this study result does not, in and of itself, refute the 'CTL hypothesis', it represents a significant disappointment for the AIDS vaccine research effort, and raises important questions about the ability of vaccine-elicited cell mediated immune responses to favorably alter the outcome of HIV infection.^{39a} There are also efforts under way to utilize the recently solved three-dimensional structure of the HIV Env glycoprotein to guide the derivation of non-native structures that might serve as better immunogens to elicit broadly cross-reactive neutralizing antibodies. In addition, relatively conserved and functionally essential sequences of the extracellular domain of the HIV transmembrane Env protein, gp41, are being explored as immunogens to elicit broadly neutralizing antibodies.

MALARIA (CHAPTER 29)

Malaria is the world's most common vector-borne disease – estimated to cause approximately 500 million clinical cases and 2 million deaths annually.^{40, 41} The disease hits hardest in Africa, and is especially severe in children under 5 years of age. In addition to direct morbidity and mortality, malaria is responsible for debilitating illness with enormous social and economic consequences. Of the four malaria-associated protozoal species, *Plasmodium falciparum* and *P. vivax* represent the two major agents. These parasites have a three-stage lifecycle taking place both within the mosquito, and in the liver and blood of the infected host, and each cycle is largely distinct from the others from an immunological perspective. As a result of the multiple strategies for evasion of host immune response that the parasite has evolved, parasite replication proceeds at high levels despite active host immune responses.^{42, 43} Either as a result of these specific immune evasion strategies or the inability of the infected human host to mount immune responses that clear the parasite, prior infection does not protect an individual from repeated subsequent infections. Although the severity of disease is often attenuated following repeated infection, the mechanism of disease modulation is incompletely understood, and the limited relative immunity engendered by prior infection is easily lost if an individual leaves a malaria-endemic region. As such, the limited impact and duration of host immune responses to malaria parasites suggest that any successful vaccine strategy will need to do far better than natural immune responses – a high bar for efforts to develop an effective vaccine.

Roughly two dozen antigens have been cloned and tested as potential vaccine immunogens, and with a few exceptions the results have been disappointing.⁴⁴ One antigen, the circumsporozoite antigen, presented as a fusion with HBsAg (RTS,S), has shown modest promise in human studies.⁴⁵ This vaccine is now undergoing larger-scale clinical efficacy testing to determine if the magnitude of protection would justify large-scale implementation efforts. Should 'proof of concept' be supported in

these studies, but the absolute magnitude of efficacy be insufficient, future efforts will likely focus on the identification of an appropriate adjuvant to improve the magnitude and duration of immune responses. Alternative approaches include immunization with irradiated or genetically attenuated sporozoites,⁴⁶ definition of novel antigens expressed at specific stages of the parasite lifecycle, and evaluation of combinations of multiple parasite antigens.

TUBERCULOSIS

Mycobacterium tuberculosis is an intracellular mycobacterial pathogen that represents one of the world's most common and most serious infectious diseases.⁴⁷ Over 2 billion people are believed to harbor latent *M. tuberculosis* infections, and approximately 8 million active cases of tuberculosis and over 2 million deaths occur each year. Furthermore, the interface of HIV infection and its attendant immune system damage both increases the severity of *M. tuberculosis* infection and increases the infectiousness of infected individuals. The emergence and dissemination of *M. tuberculosis* isolates that are resistant to multiple antimicrobial drugs represent a growing public health threat. However, while the need for a vaccine to prevent tuberculosis is clear, a significant number of challenges face vaccine development efforts.⁴⁸ Most individuals infected with *M. tuberculosis* can control the acute phase of mycobacterial replication, and mount vigorous innate and adaptive immune responses to the infection. However, the infection is often not cleared by the host's immune response, and the mycobacteria are able to persist and multiply within vacuoles inside macrophages. Long-term latency is established in fibrotic cysts in the lung. The recrudescence and dissemination of *M. tuberculosis* occur at a later time in a number of infected individuals, likely as a result of waning host immune control. Although the ability of *M. tuberculosis* to persist despite active innate and adaptive immune responses represents a major challenge to vaccine development, the fact that most individuals can contain (if not clear) *M. tuberculosis* infection suggests that a vaccine that can alter the course of the natural infection by limiting early dissemination and decreasing the risk of later recrudescence could provide major public health benefits.

Efforts to develop a vaccine against tuberculosis date back many decades. Bacille Calmette-Guérin (better known as BCG), based on *Mycobacterium bovis*, was first introduced in 1921.⁴⁹ Currently, BCG is provided as a component of the routine Expanded Programme for Immunization (EPI) schedule and is administered to a significant majority of the world's children. Although some protective efficacy (50–80%) has been reported against military infection and *M. tuberculosis* meningitis in children, conflicting results have been obtained in different studies regarding the ability of BCG to protect against pulmonary tuberculosis in adults. One explanation for the overall limited efficacy of BCG emerges from formal genome sequencing studies that have disclosed significant differences between *M. tuberculosis* and of the vaccine strain of BCG. The variability in the results of BCG efficacy studies in different populations and geographies may derive from variations in the geographic prevalence of cross-reactive mycobacterial species (that may themselves confer partial protection), or the fact that BCG vaccines used throughout the world do not represent a homogeneous preparation – with the root strain of BCG having been widely distributed and passaged extensively under diverse conditions.

Vaccine efforts against tuberculosis have primarily focused on the evaluation of specific mycobacterial antigens (e.g., ESAT6, Ag85, and HSP60) that have been tested as vaccines in animal models with variable success.^{50, 51} Some of these strategies are now being advanced into human clinical

trials. An alternative strategy is based on improving the performance of the BCG vaccine by insertion of genes encoding specific potential protective antigens that it normally lacks. In addition, the development of auxotrophic mutants of *M. tuberculosis* is being explored as a potential immunogenic and specifically attenuated live vaccine. The determination of the sequence of the *M. tuberculosis* genome nearly a decade ago helped identify numerous previously unknown gene products, and increased the repertoire of antigens to be evaluated for their ability to induce protective immune responses.⁵² The pathogen sequence is also being used to elucidate virulence determinants and thereby help guide efforts to attenuate *M. tuberculosis* rationally.

RESPIRATORY SYNCYTIAL VIRUS AND PARAINFLUENZA VIRUS (PIV)

Together with influenza virus, RSV and PIV account for a substantial majority of pediatric upper respiratory illness and consequent acute otitis media. A variety of influenza vaccines are licensed for pediatric use, but vaccines to prevent infection with the paramyxoviruses RSV and PIV remain elusive. A significant impediment to vaccine development for RSV and PIV traces back to unanticipated untoward results obtained in clinical studies of inactivated RSV vaccines in the early 1960s.⁵³ These early-generation RSV vaccines – based on cultured virus that had been inactivated with formalin – raised a potent antibody response in immunized children. However, on subsequent natural exposure to RSV, vaccine recipients exhibited more frequent and significantly more severe lower respiratory tract RSV infections than did unimmunized children. As a similar phenomenon was also seen with a formalin-inactivated measles vaccine in the same era, a common immunopathologic mechanism may be operative.⁵⁴ While the mechanism of exacerbation of RSV disease by the early inactivated vaccines is incompletely understood, it has been suggested that chemical inactivation of RSV and measles resulted in modification of a critical neutralizing structure on the surfaces of these viruses, thereby limiting the induction of the most potent neutralizing antibodies and favoring nonneutralizing and potentially immunopathologic antibody responses. (Passive protection against RSV is available for premature infants in the form of monoclonal antibodies that target the RSV F protein (one of the viral envelope glycoproteins); certain anti-RSV antibody responses can clearly mediate protective as opposed to deleterious effects.⁴⁶) Alternatively, or in addition, it has been proposed that inactivated RSV vaccines may have preferentially induced a Th2-type immune response when a Th1-type response may be needed to effect protection of the lower respiratory tract from RSV infection and damage.

While excellent live attenuated measles vaccines have been developed, RSV and PIV have so far resisted the approach used for measles and mumps (these are all members of the Paramyxoviridae family of viruses). Based on the successful precedent provided by the live attenuated measles vaccine, an attenuated or reverse genetics-engineered RSV is considered the most promising approach. However, stable attenuation of RSV has been difficult to achieve and vaccine safety concerns result in their cautious advancement through clinical evaluation.⁵⁵

NEISSERIA MENINGITIDIS GROUP B

Effective vaccines for meningococcus types A, C, Y, and W135 are available as straight capsular polysaccharides and as conjugated polysaccharides.⁵⁶ The group B polysaccharide shares chemical similarity with a shorter sugar found on the surface of neuronal tissue.⁵⁷ While it is possible

to make highly immunogenic conjugates with the group B polysaccharide, theoretical concerns about cross-reactivity with self antigens has impeded the development of this type of vaccine. Current work centers on a handful of relatively well-conserved surface proteins of meningococcus.

GROUP B STREPTOCOCCUS

GBS is a common component of the flora of the female genital tract, and transfer to the neonate is the cause of severe infections that are fatal or have serious sequelae.⁵⁸ Short-course intrapartum antibiotics are recommended for culture-positive women, and this approach has cut the incidence of neonatal infections by about two-thirds, thus reducing somewhat the urgency of vaccine development. However, short-course antibiotics could ultimately drive the emergence of antibiotic-resistant GBS. Candidate vaccines have been shown to elicit a protective response.³⁴ However, aside from a reduced market, the main impediment to development of a GBS vaccine is concern over vaccination of pregnant women or women of childbearing age. Any birth defect might be attributed to the vaccine, and in a litigious society, this would be problematic for a vaccine producer.

HEPATITIS C VIRUS (HCV)

Prior to the advent of effective polymerase chain reaction methods for screening blood donations, HCV was a significant cause of transfusion-related hepatitis. Currently, transmission of HCV among the normal population is quite low; transmission among injection drug users remains high. HCV is another pathogen where infection does not typically result in an immune response that clears the infection. However, a minority of HCV patients do spontaneously clear their infection, suggesting that an appropriate immune response could do the job. Current vaccine work is concentrated on vectored gene delivery vaccines, primarily adenoviruses, intended to raise antiviral cytotoxic T-cell responses.⁵⁹

HERPES SIMPLEX VIRUS

With the exception of the live attenuated varicella-zoster virus (VZV) vaccine used for the primary prevention of chickenpox and reactivation of latent VZV infections (the cause of shingles and postherpetic neuralgia in older individuals), there are no other vaccines available for use in humans to prevent infection with members of the herpes virus family.⁶⁰ HSV types 1 and 2 cause recurrent vesicular eruptions “above or below the belt,” respectively. Like other herpes viruses, HSV infections are not cleared by the immune system and the virus can persist, remaining in a latent state that is functionally inaccessible to immune recognition and clearance. In addition, like other herpes viruses, HSV encodes a number of gene products that promote evasion of host immune responses. Recent attempts to make HSV2 vaccines have used virus glycoproteins produced by recombinant DNA methods. A recent clinical efficacy trial of this vaccine approach showed partial protection of women, but not men, who were seronegative for HSV1.⁶¹ The reasons for this curious result are not clear, but efforts to develop this type of vaccine continue. In addition, a number of preclinical studies are exploring the ability of cell-mediated immune responses to HSV antigens induced by recombinant vaccine vectors (e.g., adenoviruses: see Novel vaccine vectors, below) to prevent or ameliorate HSV infections. Genetically engineered attenuated HSV variants have also been studied in experimental animal models. It is not clear when these new strategies may advance to clinical evaluation in humans.

KEY CONCEPTS

CONTEMPORARY OPPORTUNITIES AND CHALLENGES IN VACCINE DEVELOPMENT

The processes of vaccine development have changed significantly in recent years – a process facilitated by substantial improvements in understanding of human immune system function, as well as the advent of powerful new technologies for vaccine development. As a result of these advances, vaccine development is now commonly pursued in a hypothesis-driven manner and is a far less empiric pursuit than in the past. However, at the same time, the infectious diseases for which no effective vaccines currently exist represent more challenging targets than those diseases that have yielded to vaccine development efforts in the past. Furthermore, global changes that influence the emergence and rate of spread of infectious diseases place unprecedented challenges on the productivity and pace of new vaccine development efforts.

Current opportunities

- >> Improved understanding of human immunology (including the biology of innate immune system function, antigen presentation, and the generation and maintenance of T- and B-cell memory)
- >> Improved technologies to measure human cellular and humoral immune responses
- >> The advent of genomic and proteomic technologies for new antigen discovery
- >> The wealth of recombinant DNA methodologies that enable the isolation and characterization of protective antigens from diverse pathogens (including those that may not be successfully propagated in culture)
- >> The development of recombinant and synthetic approaches for the large-scale production of precisely defined vaccine antigens (including the ability to produce immunogens that accurately recapitulate the conformational structure of native antigens, or that, alternatively, alter them so that they serve as more effective immunogens in eliciting desired immune responses)
- >> The emergence of new mechanism-based vaccine adjuvants to enhance the immunogenicity of vaccine antigens

Current challenges

- >> The need to develop vaccines for infections where natural immunity does not often or ever develop following natural infection (e.g., human immunodeficiency virus (HIV), malaria, hepatitis C)
- >> The need to develop vaccines that protect against genetically diverse pathogen variants with a limited number of vaccine immunogens (e.g., HIV, malaria, and influenza)
- >> The need to develop vaccines for infections where concerns exist about vaccine elicitation of potentially autoimmune (*Neisseria meningitidis* group B) or immunopathologic (e.g., respiratory syncytial virus) responses by vaccination

- >> The challenge of responding rapidly and effectively, with powerful new technologies, to newly emerging infections – including those that haven't been seen in humans before (e.g., severe acute respiratory syndrome (SARs)) or for which novel antigenic variants are anticipated but cannot be predicted (e.g., pandemic influenza)
- >> Maximizing the value of innovative new approaches while ensuring the safety of new vaccines so derived

CYTOMEGALOVIRUS (CMV)

Another herpes virus, CMV is a very common infection in humans, with 50–80% of individuals being infected by adulthood. CMV is a cause of severe infections in neonates, causing debilitating neurological sequelae. Following initial infection, CMV persists in infected humans, despite the fact that anti-CMV antibodies are present and that a very sizeable proportion of the overall host CD4 and CD8 immune responses are specific for CMV antigens. Ongoing virus persistence and replication in the face of active host immune responses are likely explained by CMV's sophisticated repertoire of host immune evasion functions (including those that inhibit antigen presentation mechanisms and immune effector responses). For these reasons, to be successful, vaccine development efforts will need to elicit immune responses that are significantly more effective than the quantitatively impressive, but functionally limited, immune responses that are generated in the course of natural CMV infections. Live attenuated vaccines have been investigated sporadically since the 1970s.⁶² An attenuated strain, the Towne strain, showed some effect, but was judged to be insufficiently immunogenic. Hybrids of the attenuated Towne strain and the virulent Toledo strain remain in development. Recent work has included recombinant DNA (rDNA)-derived proteins (via either DNA vaccine approaches or recombinant viral vectors, such as attenuated poxviral vectors).^{63, 64}

EPSTEIN-BARR VIRUS

EBV is a herpes virus that represents the causative agent of infectious mononucleosis and is widespread among the human population. In concert with incompletely understood environmental (and perhaps additional host) factors, EBV is also etiologically associated with Burkitt's lymphoma. The ability of EBV to establish persistent infections in humans (along with latent infections at the cellular level) despite readily detectable antiviral immune responses suggests that, like other herpes viruses, the development of effective EBV vaccine will likely be challenging. EBV vaccines have been in development since the 1980s with the coat protein, gp220/350, as the most common vaccine antigen studied.⁶⁵

DENGUE FEVER VIRUS

Dengue fever virus is a mosquito-borne flavivirus (the virus family that includes Japanese encephalitis virus and yellow fever virus – for which successful vaccines exist). Dengue virus is endemic in a substantial portion of tropical and subtropical areas and causes febrile disease as well as hemorrhagic fever. There are four distinct serotypes of dengue fever virus. Prior infection with one serotype has been implicated in predisposing for more severe disease following infection with a second dengue fever virus serotype, although the evidence supporting this concept has been questioned and the underlying pathogenic mechanisms are incompletely understood.⁶⁶

One hypothesis proposes that antibodies against the initial infecting serotype bind to the surface of virus particles of the novel infecting serotype, but do not neutralize the infection. In a process referred to as “immune enhancement” of infection, still infectious complexes of antibody virus particles are then envisioned to be preferentially taken up by cells of the reticuloendothelial system that represent primary target cells for virus replication. Although the veracity of this hypothesis is not established, it does present certain theoretical concerns about what type of antibody responses will need to be induced by vaccines to exert beneficial rather than detrimental effects. The general belief is that a vaccine providing equivalent immunity against all four serotypes will be required. Vaccines based on inactivated virus, engineered chimeric viruses based on the yellow fever virus vaccine platform, engineered deletion mutant viruses, and rDNA-derived proteins are in various stages of development.⁶⁷

NEW ANTIGEN DISCOVERY METHODS

Historically, vaccine antigens were not discovered in the literal sense. Rather, whole organisms were inactivated by either heat or chemistry or organisms were attenuated by forcing growth in nonphysiological conditions. The entire antigenic repertoire of the organism was delivered to the immune system. The isolation of tetanus, diphtheria, and pertussis toxins, along with chemical detoxification schemes, allowed the production of more refined vaccines. The isolation and purification of polysaccharide capsules from a range of important bacterial pathogens enabled the development of additional vaccines.

With the advent of molecular biology in the late 1970s, a new set of tools allowed a more directed approach for the discovery of pathogen virulence factors, vaccine antigen discovery, and vaccine development. The tools of molecular biology enabled for the first time the development of vaccines against pathogens that could not be propagated in culture, including the successful development of recombinant HBV and HPV vaccines. Development of these vaccines was enabled by clinical and animal model studies showing that antibodies directed against a specific viral target antigen (e.g., the HBV surface antigen or the HPV L1 protein) were implicated in protection. In addition, molecular biologic approaches enabled the derivation of fully recombinant vaccine antigens (such as those developed using a limited set of defined antigens of *Bordetella pertussis*), including genetically modified versions of bacterial toxins that maintain their proper antigenic structures but are no longer toxic. However, for many of the pathogens for which vaccines do not currently exist, application of these recombinant DNA technology-enabled strategies are insufficient due to incomplete understanding of the pathogen antigens that would elicit a protective host immune response. As such, the development of additional techniques to discover protective antigens was needed. Fortunately, several important technological advances that facilitate discovery of previously unknown protective antigens from even very complex microorganisms have opened a new era in vaccine development.

The earliest rDNA technology-enabled methods of antigen discovery involved the expression of individual pathogen-derived gene products (or fragments thereof) in bacterial hosts (typically *Escherichia coli*) using rDNA expression vectors. Here, the genome of a pathogen is broken up, and the fragments are inserted into a plasmid or a viral vector, typically a lambda bacteriophage.⁶⁸ Colonies, or plaques, are spread on a membrane, allowed to grow, and hopefully express the cloned gene fragments. The

ability of these recombinant gene products (now isolated in individual colonies) to react with antibodies present in the serum of individuals who had recovered from infection with that pathogen could then be directly assessed. Antibodies present in the immune sera are assessed for their ability to identify antigens by immunochemical reactivity. In this way, the entire genome of a given pathogen could be scanned for potential immunoreactivity.⁶⁹ Such reactivity would both indicate the *in vivo* expression of that gene product, as well as document its antigenicity. However, additional studies are needed to demonstrate whether antibody responses against a newly defined antigen have any protective potential. To document the ability of an antigen to elicit protective immune responses, it is necessary to immunize an experimental animal (most commonly, mice) and then, following experimental pathogen challenge, evaluate infection outcomes in immunized versus nonimmunized animals. As this approach has most often been used to identify antigens recognized by host humoral responses, sera from animals immunized with a candidate antigen can then be transferred to a naïve host to provide evidence that the antibody response to the antigen represents the relevant agent of immune protection.

More recently, as DNA sequencing became more efficient and scaleable, determining the entire sequence of the genomes of viruses, bacteria, and parasites has become routine,^{70, 71} allowing identification of previously unknown genes (and predicted gene products) that can be evaluated as vaccine immunogens. Scanning the entire pathogen genome via specific computer analysis programs, genes that exhibit specific characteristics can be identified (e.g., predicted expression on the cell surface by virtue of possession of a leader sequence for secretion or membrane anchor sequences).⁷² In addition, the relative conservation of the gene within the pathogen population can be determined by assessment of gene sequences from multiple distinct isolates. Once potential vaccine antigens are identified, each candidate gene is expressed in an appropriate rDNA system, and the protein product is tested in an animal model.⁷³ The first bacterial genome sequenced in its entirety was that of *Haemophilus influenzae*, marking the beginning of a new approach to vaccine antigen discovery.⁷⁴ Since this initial bacterial genome sequence determination, genomic sequencing of pathogens has advanced exponentially. Over 300 bacterial genomes have now been sequenced, and hundreds more are currently in process. Genome-based antigen discovery is being applied to a wide range of bacteria, including streptococci, pneumococci, staphylococci and *Chlamydia*, as well as nonbacterial pathogens such as *Plasmodium falciparum*.⁷⁵

An alternate, promising approach to novel antigen discovery has been built on technological advances in proteomics.^{76, 77} These advances include development of high-resolution two-dimensional gel electrophoresis techniques and mass spectrometry methods that enable separation, identification, and purification of individual proteins from the complex mixture of proteins expressed by a pathogen. In proteomic analyses, a small culture of bacteria, preferably taken directly from an infected person, or otherwise grown in physiologically similar conditions, is subjected to physical or enzymatic treatment with specific proteases to generate peptide fragments that are then fractionated by a micro-high-performance liquid chromatography method and sequenced by molecular mass-by-mass spectrometry. An overlapping set of peptides of approximately 8–10 amino acids is sufficient to identify an antigen and provides the means to find the gene. Although proteomic analysis is, in some ways, more involved than genomic analysis, it provides an important new approach to antigen identification, and offers a direct way to document that the specific protein identified is actually expressed by the pathogen (including, for example, demonstration that a protein of

interest is expressed on the external surface of the pathogen).^{78, 79} A combination of proteomic and serologic methods to select potential novel vaccine immunogens, called serological proteome analysis, or SERPA,^{80, 81} can be used to screen the pathogen proteome for expressed proteins that are recognized by antibodies present in sera obtained from individuals who have recovered from an infection with the pathogen.

The proteomic approach to antigen discovery has been applied to identify novel vaccine candidates for a number of human pathogens, including *Helicobacter pylori*, *Chlamydia pneumoniae*, *Staphylococcus aureus*, *Bacillus anthracis*, *Haemophilus influenzae*, and *Plasmodium falciparum*. As in new genomic methods for antigen discovery, having identified a gene encoding a candidate antigen by proteomic methods, it is then necessary to show that an immune response of the desired type can be raised against the protein. In addition, it is necessary to show that immune responses elicited following immunization with the candidate antigen engender some degree of protection. Often, pure protein antigens produced by recombinant methods are not very immunogenic. As such, many of the emerging recombinant vaccines so produced will likely require enhancement of their immunogenicity by means of an adjuvant.

ADJUVANTS

The term ‘adjuvant’ (derived from the Latin *adjuvare*, to help) refers to any substance added as a component of a vaccine preparation – in addition to the vaccine antigens themselves – that improves the immunological response to the antigen. As such, ‘adjuvant’ is a catch-all term including a broad range of molecular entities that act via diverse – and, in a number of instances, yet to be elucidated – pathways. Until recently, most adjuvants were derived empirically and the mechanisms by which they augmented immune responses were unknown. As a result, there were few, if any, principles available to guide the improvement of known adjuvants or the development of new ones. However, recent advances in understanding of the mechanisms by which dendritic cells sense the presence of pathogens and their constituents, and translate this information to shape the quantity, quality, and durability of host cellular and humoral adaptive immune responses, have transformed adjuvant discovery and optimization. What was once a process of trial and error now represents an area of hypothesis-driven research and mechanism-based discovery.

A particularly promising advance emerged from the discovery that pathogen sensing by the innate immune system is mediated by recognition of specific pathogen-associated molecular patterns (PAMPs) by pathogen recognition receptors (PRRs) such as the Toll-like receptors (TLRs) that are expressed on dendritic cells (DCs) and other hematolymphoid and some epithelial cells⁸² (Chapter 3). The pathogen-derived PAMPs recognized by TLRs consist of structures that are found only in or on pathogens (including bacteria, viruses, and parasites) and are not part of normal vertebrate biology. Following binding of a specific PAMP to a specific PRR, a specific cellular activation and response cascade is triggered that can directly confront an intruding pathogen and/or lead to the activation of specific host adaptive immune response mechanisms. These breakthroughs in basic immunology have been readily translated into what can now be considered the science of adjuvant biology.^{83, 84}

Such progress has occurred at an especially opportune time as new vaccine development strategies have transitioned from traditional approaches using attenuated or killed pathogens to highly defined and purified recombinant proteins (so-called “subunit” vaccines) or nonreplicating vectored antigens. Although these newer approaches are promis-

ing from the perspective of vaccine safety and the opportunity they afford to design the structures of vaccine immunogens, recombinant or synthetic vaccines are often inherently less immunogenic than traditional vaccines based on attenuated live viruses or intact killed organisms. In the context of current vaccine development and regulatory approval processes, an adjuvant is developed as part of a vaccine, not as an independent product. Consequently, there are currently no adjuvants licensed by regulatory authorities as stand-alone products.

Most contemporary efforts to develop novel adjuvants are focused on the targeted activation of TLRs that are expressed on specific cells critical for the generation of innate and adaptive host responses to specific pathogens.⁸⁵ A family consisting of 10 distinct TLRs has been identified to date in humans (Chapter 3). TLRs are expressed in a number of innate immune cells, including DCs, macrophages, neutrophils, endothelial cells, and fibroblasts. Given the importance of DCs as critical antigen-presenting cells, most studies of the biology of TLR signaling have focused on these cells. Different TLRs are expressed on distinct subpopulations of DCs, and, depending on the TLR, in distinct cellular compartments. TLRs expressed on the surface of human myeloid DCs include TLR2 (which is heterodimerized with TLR 1 or 6), as well as TLRs 4, 5, 6, and 10 (Fig. 92.6), while these same cells express TLRs 3 and 8 within endoplasmic reticulum (ER) and phagolysosomes. Plasmacytoid DCs (pDCs) express TLR7 and 9 within ER/phagolysosomes. The TLRs expressed on the cell surface are primarily activated by PAMPs encountered in the extracellular environment, while TLRs expressed in the ER/phagolysosomes are activated by PAMPs (including viral pathogen-derived RNA or DNA) that tend to be routed through these endosomal compartments. Activation of TLRs on innate immune cells leads to their production of specific cytokines, as well as their expression of co-stimulatory molecules, leading to induction of adaptive immune responses. Given that different DCs express different TLRs, and that signaling via different TLRs results in the expression of a distinct pattern of cytokines, it is believed that activation of specific TLRs can variously favor the induction of Th1- or Th2-biased immune responses, or can differentially augment either direct or cross-presentation pathways for antigen presentation (Fig. 92.6). Although most data on induction of specific types of immune responses by engagement of specific TLRs have emerged from murine studies (and have not yet been validated in humans), the ability to tailor an adjuvant preparation to achieve a desired type of immune response with a specific vaccine immunogen is a promising notion. Naturally occurring ligands for TLRs include lipopolysaccharide (LPS) from bacterial cell walls (recognized by TLR4), triacyl lipopeptides (recognized by TLRs 1+2), diacyl lipopeptides (recognized by TLRs 1+6), peptidoglycan (recognized by TLR2), flagellin (the monomer that makes up flagella, recognized by TLR5), single-stranded RNA (recognized by TLR7), double-stranded RNA (recognized by TLR3), and unmethylated DNA containing the dinucleotide pair CpG⁸⁶ (recognized by TLR9). Based on these insights, a variety of approaches to develop adjuvants predicated to activation of specific TLR pathways are being actively pursued.

One interesting aspect of adjuvant development is how it is revealing the mechanisms of action of adjuvants that were originally identified via a process of trial and error, as well as delineating important aspects by which certain empirically derived vaccines are able to induce high-level, long-lasting immune responses. One illustrative example can be found in the case of complete Freund’s adjuvant (CFA), which has long served as

the benchmark for laboratory studies of adjuvants. CFA is a mixed emulsion of mineral oil, mannide monooleate, and killed mycobacteria. However, it is far too reactogenic for use in humans, causing significant pain and abscesses at the site of injection – reactions that would be exacerbated if CFA were to be used repeatedly. An alternative preparation termed incomplete Freund's adjuvant (IFA) lacks the mycobacterial component, but it too is associated with injection site reactions that are severe enough to limit its use to experimental therapeutic cancer vaccines. Although CFA's toxicity precludes its use as a vaccine adjuvant in humans, many of its constituents (including liposaccharides, DNA, and specific bacterial cell wall components) are now understood to exert their adjuvant effects on vaccine-induced immune responses via engagement of specific TLRs. Similarly, the live attenuated *Mycobacterium bovis* strain, BCG, long widely employed as a vaccine for the prevention of

tuberculosis, includes cell wall, peptidoglycan, and DNA components that activate specific TLRs. Interestingly, the highly effective yellow fever vaccine 17D has been shown to activate multiple TLRs as part of its induction of antiviral immune responses.⁸⁷ It is quite likely that other live attenuated viruses that transiently replicate in immunized hosts also activate innate immune responses via engagement of TLRs. In yet another example involving a nonreplicating vaccine immunogen, one version of the Hib polysaccharide conjugate vaccines now licensed for use in children for the prevention of invasive Hib disease includes the meningococcal outer-membrane protein complex (OMPC) as its protein carrier. OMPC conjugates have favorable immunogenic properties that correlate with the ability of OMPC to activate DCs via TLR2.⁸⁸

Hundreds of different adjuvant formulations have been tested in animal models, and a few have been advanced into human studies. With a few

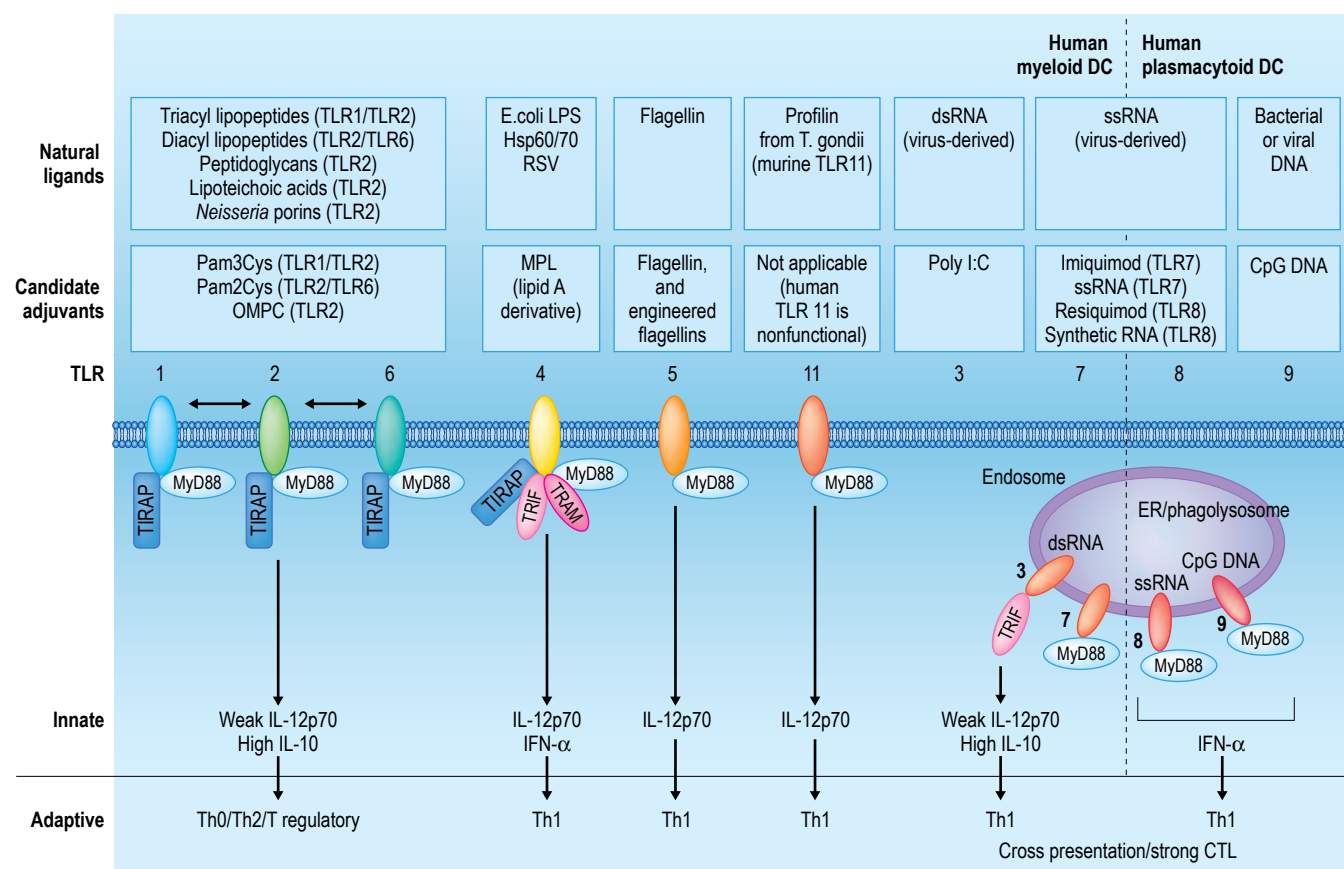

Fig. 92.6 Toll-like receptor (TLR) signaling pathways and mechanism-based adjuvants. The targeted activation of specific dendritic cell (DC) populations via engagement of specific TLRs to initiate innate and adaptive immune responses represents a very promising approach for the development of novel adjuvants based on natural or synthetic versions of the pathogen-associated molecular patterns (PAMPs) that trigger specific TLRs. Specific TLRs and their natural activating ligands are shown above. Different TLRs are associated with different adaptor proteins that propagate intracellular signaling along distinct pathways which favor specific immune responses (e.g., Th1, Th2, cross-presentation or CTL priming). The character of responses from specific TLR engagement illustrated is based on animal and *ex vivo* studies. In humans, TLRs 7 and 9 are expressed in the endoplasmic reticulum (ER)/phagolysosomes of plasmacytoid DCs (pDCs) that represent the major sources of type I interferon production (e.g., IFN- α). Human myeloid DCs (mDCs) express TLR3 (in the ER/phagolysosomes); and TLR2 (heterodimerized with TLRs 1 or 6), and TLRs 4, 5, 8, and 11 on the cell surface. (Adapted from Pulendran B, Ahmed R. Translating innate immunity into immunologic memory: implications for vaccine development. *Cell* 2006; 124: 849–863, with permission from Elsevier.

notable exceptions, these formulations have not yet been licensed as a vaccine. Major classes of adjuvants now available and in development include: (1) alum; (2) liposomes; (3) immune-stimulating complexes (ISCOMs); (4) virosomes; (5) emulsions; (6) cytokines; and (7) Toll-receptor agonists.

Alum

Alum, the classical adjuvant most often used in vaccines in humans, includes a range of salts of aluminum precipitated under basic conditions, usually aluminum sulfate mixed with sodium or potassium hydroxide plus a variable amount of phosphate.⁸⁹ The relative proportions will determine the size, charge, and solubility of alum. The composition of alum used as an adjuvant varies in currently available vaccines and may influence vaccine immunogenicity. Alum is utilized as an adjuvant in many of the currently available vaccines composed of inactivated toxins or recombinant proteins (live attenuated vaccines do not include alum or other adjuvants).

Alum serves two main purposes as an adjuvant. First, it acts as an antigen depot. Vaccine antigens adsorb to alum and elute from it following injection into the host. Second, alum acts as a mild irritant, causing the recruitment of leukocytes necessary for generation of an immune response to the site of injection. Adsorption of antigens on to alum routinely improves immunogenicity, particularly the antibody response. Alum does not typically enhance CD8 T-cell responses. Alum has been a component of many vaccines for decades and has an excellent safety record. As new adjuvants are developed, alum may remain as a component of combination adjuvant mixtures (as is the case with some newer adjuvants now approaching clinical use), or it may eventually be supplanted by other agents that more effectively provide favorable depot and local inflammatory responses to accentuate host immune responses.

Liposomes

Using lipids with polar head groups (e.g., triglycerides) and differing types of hydrophobic tails, one can form either micelles (spheres) or multilamellar sheets in aqueous environments.⁹⁰ Under the right conditions, antigens can be incorporated into the spheres or between layers of the sheets, providing a potential slow-release depot system. Immunopotentiators such as QS21 or detoxified LPS derivatives (such as monophosphoryl lipid A (MPL)) may be added to the lipid mix.⁴⁵

Immune-stimulating complexes

ISCOMs are a proprietary form of liposomes made of cholesterol, saponins from *Quillaia* bark (various members of the QS-X family of triterpene glycosides), and phospholipids that form cage-like structures into which antigens can be entrapped or intercalated.⁸⁶ ISCOM complexes may provide a depot function, as well as facilitate the delivery, uptake, and processing of vaccine immunogens by APCs.

Virosomes

Purified influenza virus hemagglutinin (HA) and neuraminidase mixed with phosphatidyl choline and phosphatidyl ethanolamine (polar lipids) will form empty particles that have the surface properties of influenza virus. Adding an antigen in solution before mixing the lipids results in the incorporation of the antigen inside the particle. This provides a vehicle for delivering antigens to the interior of a cell, via the influenza HA membrane

fusion process, thereby enabling antigen processing and presentation via both major histocompatibility complex (MHC) class 1 and 2 pathways.⁹¹

Emulsions

Numerous oil-in-water and water-in-oil emulsions have been tested as adjuvants. One such emulsion, MF59, is used in a licensed influenza vaccine. MF59 consists of squalane, a metabolizable shark oil and two surfactants, polyoxyethylene sorbitan monooleate and sorbitan trioleate, in an oil-in-water emulsion.⁹²

Cytokines

Cytokines are host-produced immunomodulators that regulate immune cell action (Chapter 10). Several cytokines are being tested as potential vaccine adjuvants, including granulocyte-macrophage colony-stimulating factor (GM-CSF), interleukin-2 (IL-2), and IL-12.

Toll-receptor agonists

Of the defined TLR agonists being explored as vaccine adjuvants, LPS and its partially detoxified form, MPL, which activate TLR 4, have been most thoroughly explored in clinical trials. With evidence of enhanced ability to increase the percentage of individuals responding with protective antibody levels to hepatitis B as compared to a standard hepatitis B vaccine, one hepatitis B vaccine that employs an adjuvant formulation (termed AS04) consisting of a combination of alum and MPL⁹³ has been licensed for use in high-risk individuals. In addition, a vaccine against HPV that uses the same adjuvant formulation may be licensed soon, and candidate HSV-1 and malaria vaccines currently being studied in late-stage clinical trials also include this alum-MPL combination adjuvant.

A wide variety of TLR9-specific agonists consisting of oligodeoxynucleotides containing unmethylated CpG motifs (CpG-ODN) are being evaluated in preclinical studies. These CpG-ODNs resemble bacterial DNA, modified to include a phosphorothioate backbone to increase their stability. Two CpG-ODN adjuvants have been evaluated in recent phase I and II trials and shown to increase the timing and magnitude of induction of protective antibody levels, as well as the proportion of responding individuals, to recombinant HBSAg vaccine as compared with the current commercially available version of the vaccine.⁹⁴ One of these CpG-ODN adjuvants also elicits protective antibody responses in immunized HIV-infected individuals who had previously failed to respond to the hepatitis B vaccine. This approach is now being studied as a way of inducing protective immune responses to hepatitis B earlier after initiation of the vaccination regimen or with fewer doses of the vaccine.

In addition to the CpG-ODN-based TLR9 adjuvants described above, small chemical compounds with structures that resemble nucleic acid bases have been identified that activate TLR7 (e.g., imiquimod) or both TLR7 and 8 (e.g., resiquimod). These compounds are being evaluated as vaccine adjuvants in preclinical studies. Flagellin, a TLR5 agonist, is also being explored as an adjuvant.

Recently, attention has also been focused on coupling, rather than mixing, TLR agonists to antigens. CpG oligonucleotides conjugated to antigens have been tested in preclinical studies of hepatitis B vaccines⁹⁵ and in human clinical trials for treatment of allergy.⁹⁶ Ligands for TLR7/8 have been coupled to HIV antigens,⁹⁷ and the ligand for TLR5 (flagellin) has been fused to a variety of antigens.^{98,99} In some instances,

coupling a TLR ligand to an antigen resulted in a substantial improvement of the immune response compared to mixtures – potentially the result of enabling the antigen and the TLR ligand to co-locate in the same DC compartments.

Numerous preclinical studies have confirmed that many natural and synthetic TLR agonists possess adjuvant activity. Importantly, early human clinical trials of TLR-predicated adjuvants have supported the promise of this approach to mechanism-based strategies to augment vaccine immunogenicity. An important challenge is to define the most potent and best-tolerated variants, and to define rules by which activation of specific TLR pathways might translate into predictable augmentation of desired types of immune responses. It is hoped that general rules will emerge to suggest which of an increasing number of novel adjuvants in development performs best with which type of vaccine immunogen, and if results obtained with a specific type of immunogen–adjuvant combination can be extrapolated to predict the likelihood of enhanced immunogenicity with other vaccines. Although beyond the reach of available experimental results, the ability to tailor, titrate, and otherwise optimize immune responses to vaccines by manipulation of specific TLR pathways appears a realistic future possibility. However, important challenges remain. In particular, a primary challenge for next-generation adjuvant development is finding a combination that retains immunopotentiating action while minimizing vaccine-associated adverse experiences. Short-term adverse experiences, such as local injection site reactions, represent undesirable side effects that may disqualify candidate adjuvants early in clinical development. However, given that vaccines are administered to healthy people to prevent potential future infectious diseases, the potential for rarer adverse experiences (such as autoimmunity) that may only be manifest with much longer latency from the time of vaccine adjuvant administration will undoubtedly be important considerations for use in prophylactic vaccines.

NOVEL VACCINE VECTORS

As induction of cell-mediated immune responses is considered an important component of vaccine strategies for many diseases for which no vaccines are currently available (many of which are caused by intracellular pathogens), there is a need to develop safe and readily scalable approaches to elicit durable CD8 T-cell responses in immunized humans. Further, given the critical role that CD4 T cells play in induction, differentiation, and maintenance of CD8 T-cell responses, any such novel vaccine strategy will likely also require appropriate CD4 T-cell responses. As elicitation of CD8 T-cell responses against a foreign antigen usually depends on the *de novo* expression of the antigen within a host cell and its subsequent processing and presentation via class I MHC pathways (Chapter 6), most novel vaccine strategies are predicated on the need to achieve synthesis of pathogen-derived antigens within APCs of immunized human hosts. With an increasing appreciation of the role that cross-presentation pathways can play in elicitation of class I-restricted CD8 T-cell responses, such *de novo* antigen synthesis may not need to occur within APCs themselves (which may be an advantage for potential vaccine delivery strategies that do not directly target APCs).

One of the many attractive attributes of effective live attenuated vaccines is their ability to recapitulate (to various degrees) many of the processes that lead to the generation of potent immune responses following natural infection. These processes include the fact that replication of

all viruses depends on gaining access to host cells for genome replication and for the synthesis of essential components of virus particles that permit further propagation of the infection within and between hosts. One immunologic benefit of this requirement is that *de novo* synthesis of viral gene products within infected cells provides a key opportunity for viral antigen presentation (via MHC class I pathways) and elicitation of antiviral cellular immune responses. Along with the processing and presentation of intact virus proteins via MHC class II pathways leading to production of antiviral antibody responses, live attenuated viral vaccines have a strong track record for induction of broad cellular and humoral immune responses that likely both contribute to conferring protective immunity. However, despite their track record of success, it is likely that few, if any, new live attenuated viral vaccines will be derived in a manner that resembles previous successful efforts (e.g., the empiric derivation of live attenuated polio, yellow fever, or varicella-zoster vaccines). Important reasons for this change include the desire for safe and well-characterized vaccines whose mechanisms of attenuation are defined and that can be monitored in the course of vaccine production and use. Indeed, most of the recently developed live attenuated vaccines were derived using new approaches for genetic reassortment (Fig. 92.4) wherein genome segments encoding pathogen-derived antigens of interest are recombined with a common set of genome segments that carry attenuating mutations (derived either by use of attenuating viral passage under specific conditions in cell culture (e.g., the cold-adapted influenza vaccine or use of a virus obtained from a nonhuman host that is itself inherently unable to replicate to high levels in humans, e.g., the reassortant rotavirus vaccine prepared via genetic reassortment between human and bovine rotavirus strains (Fig. 92.4)¹⁰⁰). Although such approaches have proven successful, they are limited in that they can only be applied to homologous viruses (e.g., those derived from the same virus type) whose genomes are segmented and capable of ready genetic reassortment in culture, or to viruses that can be manipulated by reverse genetics.

In response to the desire to produce vaccines that can safely and reliably elicit desired immune responses, especially T-cell responses, several approaches are being explored to develop novel vector systems that permit the expression of pathogen-derived antigens. As many of these approaches are based on viruses distinct from the viral pathogen targeted for induction of host immune responses, the inserted pathogen-derived gene products are expressed via recombinant methods as heterologous antigens. Alternatively, in nonviral expression systems, such as DNA vaccines, the pathogen-derived antigen is expressed in isolation and does not depend on virus-mediated antigen delivery to APCs following host inoculation.

Collectively, such recombinant heterologous expression systems are commonly referred to as ‘vaccine vectors.’ In some instances, such recombinant vectors express only a specific antigen (in the case of DNA vaccines or certain viral vectors, e.g., adenovirus), while in others both the inserted pathogen-derived antigens and antigens encoded by the viral vector ‘backbone’ are expressed (e.g., poxvirus vectors). Most new approaches employ expression systems that are inherently nonreplicating (e.g., DNA vaccines) or that employ viral vectors that can replicate at high levels in tissue culture but not *in vivo* (e.g., complemented adenovirus deletion variants or host range-restricted poxviruses). While numerous approaches are being pursued to develop novel vaccine vectors, they will all need to meet certain common criteria to emerge as vaccine approaches applicable for widespread use. In particular, any successful approach must be safe in healthy and immunodeficient humans (given

their increased representation in the population as a result of HIV infection and therapeutic immunosuppression), desirably immunogenic (including in individuals who may have been previously exposed to the virus from which the vector was derived, e.g., vaccinia or adenovirus), and able to be produced in large quantities and in a stable manner. A limited number of vaccine vector approaches now being pursued are likely to meet these criteria.

Should successful approaches emerge, there will likely be interest in applying them for use in vaccines targeting diverse pathogens. Thus, while definition of promising, broadly applicable, vaccine vector approaches may help simplify certain aspects of vaccine regulatory review and manufacture, they may also present challenges to prioritize use for specific applications should administration of a given vaccine vector on one occasion compromise or preclude successful administration at a later time. Nevertheless, the development of novel vaccine vectors is laying essential groundwork for the development of next-generation vaccines.

Several novel vaccine vectors currently being studied in preclinical studies and human clinical trials are described below, all of which depend on the delivery and expression of a candidate pathogen-derived gene sequence. In a number of ways, DNA vaccines represent the simplest approach to deliver pathogen-derived genes. Viral vectors similarly serve to deliver pathogen gene sequences to host APCs, either directly or indirectly, but do so in a manner that depends on and takes advantage of the lifecycle and tropism of the virus that is being adapted to express the exogenous pathogen gene products.

DNA vaccines

The ability of purified plasmid DNA containing heterologous antigens expressed under the control of eukaryotic transcriptional regulatory and RNA processing signals to elicit immune responses when injected into experimental animals was discovered serendipitously.¹⁰¹ However, since the initial, quite surprising, description, the development of so-called DNA vaccines has become an active area of preclinical and clinical vaccine development.¹⁰² Reasons for this enthusiasm include the attractive simplicity and facile preparation of vectors that encode only the defined antigen of interest (which can itself be manipulated via recombinant methods to assume a desired configuration), a reasonably straightforward method for vaccine production, and the inherent stability to temperature (which is much greater than most currently live or subunit vaccines). Although the DNA vector is most commonly injected intramuscularly, the generation of specific immune responses depends on the uptake of the vector DNA by APCs followed by the expression, processing, and presentation of vector-encoded antigens. As tissue and tissue fluids present a hostile environment for purified DNA, and the process of DNA uptake by APCs appears to be relatively inefficient, much of the dose of injected DNA is degraded before it can be reached by an APC that can initiate the desired immune response.

Most DNA vaccine research has been pursued in mice, although studies have now been performed in numerous animal species. Studies have usually utilized intramuscular injection of vaccine vector DNA, but various intradermal and transdermal approaches have also been explored. Murine studies have shown that administration of antigen-encoding plasmid DNA can elicit appreciable cellular and humoral immune responses that may confer protection against experimental challenge. However, translation of these promising results in animal models to humans has proven frustrating. While DNA vaccines have been generally well tolerated in

immunized volunteers, in most human studies of DNA vaccines, administration of even substantial quantities of DNA vaccine vectors has elicited relatively low-level immune responses. It is not yet known whether these disappointing results reflects fundamental differences in the immunogenic behavior of DNA vaccines in humans and mice, or the fact that the DNA doses administered to humans do not match those administered to mice (DNA per weight of the immunized host). Given the substantial size differences between humans and mice, it would likely be impractical (for reasons of both vaccine supply and the actual process of administration of sufficiently high doses of DNA) to administer the relative murine dose to humans. As such, a variety of approaches are being explored to prolong DNA survival in tissue, promote more efficient targeting of DNA to APCs, or to develop novel adjuvants that might specifically amplify immune responses to DNA vaccines.^{103,104}

DNA vaccines are currently being used as candidate preventive vaccines for a wide variety of infectious diseases, including HIV, tuberculosis, malaria, and CMV.

Poxviruses

Poxviruses represent the family of viruses that are physically the largest viruses and that possess the largest genomes. Much of the poxvirus genome encodes gene products that serve to evade host immune responses, and that are not required for virus replication in tissue culture. Further, facile techniques for the insertion and deletion of specific viral genes have been developed. The ability to accommodate sizeable foreign gene inserts is, in part, a function of the large size of the poxvirus genome (and the large packaging capacity of poxvirus virions). As a result of these favorable attributes, poxviruses have been utilized extensively in laboratory studies of virus biology, recombinant protein production, and host immune responses.¹⁰⁵ Although poxviruses encode multiple gene products that help the virus evade host immune responses, they are, nevertheless, potent immunogens. Studies of individuals immunized decades ago with vaccinia virus (in the course of smallpox eradication efforts) have shown that this virus induces long-lasting memory T- and B-cell immune responses.

In contrast to most of the other viral vectors currently being developed, poxviruses can replicate readily in culture and do not require an engineered host cell to support propagation *ex vivo*. One important limitation of all poxvirus vectors developed to date is that, given the large size of the poxvirus genomes and the multitude of gene products they naturally express, even large inserts derived from foreign pathogens of interest will present only a minority of the vaccine vector antigens delivered to and recognized by the host immune system. To be effective, approaches to focus immune responses on the antigen of interest will need to be developed. Toward this end, a variety of so-called 'prime-boost' ¹⁰⁶ approaches are being explored where the host immune response is primed with one type of recombinant vaccine vector (such as a DNA vaccine or adenovirus vector) and then boosted with subsequent delivery of poxvirus vectors encoding the same antigen. In this manner, immune responses to antigens of interest have been significantly augmented in a number of preclinical studies.

Vaccinia virus represents the prototypic vaccine vector. This virus is the same one that was employed in the successful smallpox eradication campaign, and has been used as a laboratory tool for decades. However, given current high expectations for vaccine safety, and the increased number of immunodeficient individuals present in the population (as a result of the

emergence of the HIV pandemic and the increased use of immunosuppressive therapies in clinical medicine) at high risk of serious adverse events, and potentially fatal consequences, from vaccinia immunization, the original vaccinia strains used in smallpox eradication efforts are not considered safe for general use. However, studies of vaccinia-based vaccine vectors have provided a strong basic foundation for research on other more highly attenuated poxvirus variants.

Modified vaccinia Ankara (MVA) is an attenuated vaccinia virus that was originally derived by prolonged passage of a vaccinia virus isolate on chicken embryo fibroblasts in culture. In the course of extensive passage in culture, a viral variant emerged that had fortuitously deleted large sections of the viral genome, including those that encode important poxvirus immune evasion genes and those that determine the ability of the virus to replicate on cells obtained from different animal species. Specifically, while MVA grows well on chicken cells, it cannot replicate in human cells in culture or *in vivo*, conferring an inherent safety feature.

MVA was safely administered to over 100 000 individuals at high risk of adverse consequence for vaccinia immunization toward the end of the smallpox eradication effort. More recently, it has garnered renewed interest as a potential safer smallpox vaccine in the wake of concerns about bioterrorism threats. Even though MVA cannot replicate in mammalian cells, the virus demonstrates favorable immunogenic properties. MVA has been used as a vector expressing genes for a wide variety of genes, including HIV and malaria antigens either alone or, as described above, in 'prime-boost' regimens, where MVA has been administered following initial priming immunizations with other vaccine vectors. A concerted effort is under way to improve further the performance of MVA by manipulating a series of poxvirus genes that dampen the human immune response to the virus (and to any antigens inserted in it).¹⁰⁷

Avipox is a family of poxviruses that infect birds and cause respiratory diseases in poultry. Canarypox, a member of the avipox group, has been adapted as a vaccine vector. Canarypox replicates well on avian cells in culture but cannot replicate on human cells in culture or in humans *in vivo*. As a result, canarypox, like MVA, provides an interesting vector system with inherent safety features.¹⁰⁸ Canarypox vectors carrying HIV genes have been tested in several clinical studies, either alone, or in 'prime-boost' regimens following priming with adenovirus vectors and recombinant protein antigens. In a large ongoing phase III HIV vaccine trial, a recombinant canarypox vector is being used as a priming vector, followed by boosting with a recombinant version of the HIV gp120 surface Env protein. To date, the results from human clinical trials of canarypox vectors have been disappointing, with only low-level specific immune responses generated in human volunteers.¹⁰⁹

Adenoviruses

Adenoviruses, one of the common causes of upper respiratory and gastrointestinal infections, have seen extensive use in clinical trials and were one of the first gene therapy vectors.¹¹⁰ Most adenovirus vectors currently being studied in preclinical and clinical settings are disabled by deletion of the early E1 genes that are necessary for replication in an immunized host. Most adenovirus vaccine vectors developed have used the well-characterized and readily produced adenovirus serotype 5 (Ad5) as the vector 'backbone.' Disabled adenovirus vectors are grown in cells that express the E1 genes artificially inserted into the cell's genome.¹¹¹ Once these disabled vectors, encoding a heterologous pathogen-derived antigen of interest, enter a cell, the pathogen gene product is expressed,

processed, and presented by host APCs. As adenoviruses can directly infect dendritic cells, they promise to provide efficient vaccine vectors. Robust antibody and CD8 T-cell responses to heterologous antigen genes expressed by adenovirus vectors have been observed in preclinical animal models. Furthermore, in early-phase human clinical trials, adenovirus vectors have been generally well tolerated, and proven to be the most effective of any recombinant vector system studied to date in eliciting high-level CD8 T-cell responses.

The main potential drawback to widespread use of adenovirus vectors in humans is that, depending on the adenovirus type and the geographic location, variable levels of pre-existing immunity are found in humans as a result of prior naturally acquired adenovirus infections. High levels of antibody against the adenovirus vector might blunt the immunogenicity and efficacy of an adenovirus vector-based vaccine, but it remains to be seen if this will be a significant limitation.¹¹² Should pre-existing immunity to adenovirus vectors derived from epidemiologically prevalent serotypes (e.g., Ad5) limit vaccine immunogenicity, current efforts to develop vaccine vectors based on serotypes that are rare in human populations or novel adenovirus vectors specifically designed to avoid pre-existing antibody responses may yield effective alternative approaches.

Adenovirus vectors are currently used in clinical trials for vaccines against HIV,¹¹³ malaria, influenza, and a range of other pathogens.

Alphaviruses

Alphaviruses are RNA viruses that cause zoonotic diseases, such as Venezuelan equine encephalitis. These viruses do not normally circulate in humans, so immunity to these viruses is quite rare in humans. Alphaviruses have a strategy for overexpressing the proteins that make up the virion by making a separate subgenomic RNA specifically encoding these gene products. Current recombinant alphavirus vaccine vector strategies take advantage of this subgenomic transcript, replacing the viral genes with selected genes for other antigens, but maintaining the signals for translation and protein production. In addition, through use of genetic complementation, it is possible to generate virus particles that only contain this heterologous antigen-encoding expression cassette. Such virus particles can efficiently mediate infection of host cells, but because they lack other alphavirus genes needed for virus replication cannot spread beyond the initial target cell infected.^{114, 115} Alphavirus vectors rival the adenoviruses in efficiency of protein production in tissue culture and have induced robust antibody and T-cell responses in preclinical studies.¹¹⁶ One current limitation of the alphavirus vector system is the difficulty of scaling the production system; however, this is a technical matter that should be addressable. In addition, ample safety data will be needed before widespread use of alphavirus vaccines achieves endorsement by regulatory authorities for use in healthy populations.

Adeno-associated virus

Adeno-associated viruses (AAV) belong to a family of single-stranded DNA viruses (parvoviruses) that include the B19 parvovirus that causes a rash in children known as 'fifth disease' (measles, mumps, rubella, and varicella make up the first four). AAV is transmitted in conjunction with adenovirus infection, and is not known to cause any significant disease. It is poorly immunogenic in the course of natural infections.¹¹⁷ AAV can integrate into the genome of the infected cell, usually in a particular place on chromosome 19, although integration

KEY CONCEPTS

VACCINE APPROACHES BEING EXPLORED TO IMPROVE ON NATURAL IMMUNITY

For many important infectious diseases for which no vaccines are currently available, successful derivation of effective vaccines will depend on improving upon natural immunity, especially in those instances where natural immunity does not follow natural infection (such as human immunodeficiency virus (HIV) and malaria) or where safety concerns limit the development of specific protective antigens (*Neisseria meningitidis* group B). In addition, for other pathogens that typically manifest significant genetic (and antigenic) diversity (such as influenza, HIV, and bacteria such as *Streptococcus pneumoniae*), a need exists to develop novel vaccines that can protect against a wide range of variants with a limited number of vaccine immunogens. Towards these ends, a number of new approaches, enabled by new vaccine technologies, are being pursued, including:

- >> Targeted alteration of protective antigens to increase their ability to elicit protective immune responses (e.g., efforts to alter the structure of the HIV Env glycoproteins gp120 and gp41 so that they elicit higher-level, more potent, neutralizing antibody responses than their native counterparts)
- >> The development of synthetic consensus antigens able to elicit broader immune responses than would sequences obtained from individual pathogen isolates (e.g., efforts to develop consensus immunogens able to elicit cytotoxic T-lymphocyte (CTL) responses against genetically diverse HIV-1 variants)
- >> Techniques for new antigen discovery to identify novel conserved antigens within otherwise genetically diverse pathogens (e.g., *Streptococcus pneumoniae*) or those for which currently known protective antigens cannot be developed as vaccines (e.g., *Neisseria meningitidis* group B)
- >> The use of novel adjuvants or vaccine vectors to enable generation of higher-level and/or more functional immune responses to pathogen antigens by vaccination than are seen following natural infection, and to enable high-level, fully functional memory immune responses to be activated at the time of initial infection (e.g., efforts to elicit high-level HIV-specific or hepatitis C virus-specific CTLs by recombinant viral vectors)
- >> Use of novel methods to shift relative immunodominance of specific pathogen gene products to increase the immunogenicity of conserved antigens from otherwise diverse pathogen genomes that are typically poorly immunogenic in the course of natural infections (e.g., efforts to augment the antibody response to the influenza A virus M2 protein via the use of potent adjuvants or conjugation to immunogenic carrier proteins)

does not appear to be efficient or site-specific when replication-defective adenoviruses of the type being developed as vaccine vectors are used. The propensity for chromosomal integration and poor immune response to the virus made AAV a good candidate for gene therapy; cells with an integrated viral genome could deliver a gene

product for a long time without the immune system killing the infected cell. Recently, efforts have been made to adapt replication-defective AAV as a vaccine vector. Although encouraging results have been reported in preclinical studies, phase I studies in humans have demonstrated disappointing immunogenicity.

SUMMARY

The challenges to optimizing the full public health potential of existing vaccines largely relate to programmatic considerations. In contrast, the terrible impact of infectious diseases that cannot now be prevented by vaccines (such as the 'big three' killers of HIV, tuberculosis, and malaria) pose direct challenges to the scientific community to develop new generations of vaccines that overcome the largely biological obstacles to control and elimination of these diseases. The nature of the challenges posed by such pathogens necessitates that future vaccine efforts will not simply recapitulate the immune responses engendered by natural infection (as has been the premise of traditional vaccine development efforts), but rather, substantially improve upon them.

As the development of vaccines to prevent infections with the so-far refractory pathogens is pursued, improved understanding of the immune response to natural infection, as well as delineation of the reasons why host immune responses fail either to clear incipient infections or prevent future new ones, will be essential. Fortunately, early empiric approaches have now been replaced with hypothesis-driven strategies enabled by improved insight into the functioning of the human immune system, as well as new technologies, including higher-resolution tools to describe and quantitate pathogen-specific immune responses; novel methods for antigen discovery and targeted optimization of immunogenicity; the development of new, mechanism-based adjuvants; and the advent of innovative methods for vaccine vector-mediated antigen delivery. Thus, although the challenges may be vexing, the scientific and technical foundations on which vaccine development efforts rest have never been stronger.

Immunotherapy of allergic disease

Anthony J. Frew

93

Specific allergen immunotherapy (SIT) involves the administration of allergen extracts to modify or abolish symptoms associated with atopic allergy. The general principles of managing allergic conditions are to make an accurate diagnosis, to identify relevant trigger factors, to institute appropriate interventions in order to reduce the impact of those triggers, and to control symptoms and disease progression. Allergen avoidance measures may be helpful, but may be difficult to implement, and are rarely sufficient to allow patients to do without other therapy. Drug treatments can be very effective, but only work as long as they are taken, so there is clearly a need for additional and long-lasting therapy. SIT is the only current therapy that modifies the immune response to allergens. The process is specific, in that the treatment is targeted at those allergens recognized by the patient and physician as responsible for symptoms. While claims for bystander benefits have been made, there is little convincing evidence that treating for one allergen will alleviate symptoms caused by a different allergen. Before deciding to use SIT it is therefore essential to assess the patient's condition carefully, with particular emphasis on the role of allergic triggers.

SIT was pioneered at the end of the 19th century and then reported formally in 1911 by Noon and Freeman at St. Mary's Hospital, London.¹ Immunotherapy then became popular in North America and in Europe, but some differences in practice have gradually developed either side of the Atlantic. In particular, American allergists tend to treat for all sensitivities identified on skin testing, using mixtures of extracts prepared from bulk vials, whereas in Europe patients are normally only treated with a single allergen, which is supplied direct from the manufacturer. Mixed allergen extracts are available and used in some parts of Europe, but only as custom mixes from manufacturers. Another difference in clinical practice is that allergen extracts used in Europe are usually dialyzed to remove low-molecular-weight components, and are standardized according to their ability to elicit a wheal, whereas in the USA, extracts may not be dialyzed and standardization is based on ability to elicit erythema rather than wheal.

Whichever form of extract is chosen, patients are started on a very low dose of allergen, and the dose is then increased, usually at weekly intervals until a plateau or maintenance dose is achieved. The maintenance dose is then given at 4–6-weekly intervals for 3–5 years. Alternative induction

regimes may give several doses on each day (semi-rush protocol), or may give the whole series of incremental injections in a single day (rush protocol). The main drawback to rush and semi-rush protocols is the risk of adverse reactions, which are much commoner than in conventional protocols. On the other hand, full protection can be attained in a few days as compared to the 3 months required in the conventional regime. Normally the doses are given by subcutaneous injection, but in recent years there has been an upsurge of interest in alternative routes of administration, especially the sublingual route, which is popular in Italy, France, and Germany and is gaining ground elsewhere in Europe, but not yet in the USA.

■ MECHANISMS ■

Several mechanisms have been proposed to explain the beneficial effects of immunotherapy (Table 93.1). Following subcutaneous injection of allergen extracts, a small proportion of the allergenic material is taken up by phagocytic cells and carried to the regional lymph nodes. The process is fairly inefficient and less than 1% of a radiolabeled dose actually reaches the lymph nodes. Almost all studies have shown that SIT induces allergen-specific immunoglobulin G (IgG) antibodies that increase progressively over the course of treatment. This has led to suggestions that SIT might work by inducing antibodies that intercept the allergen and “block” the allergic response. In patients treated for venom anaphylaxis, the development of allergen-specific IgG antibody correlates with clinical efficacy but, for other allergens, the magnitude of the IgG response is not closely related to the degree of efficacy. Moreover, the rise in IgG follows the onset of clinical benefit, rather than preceding it. Initially there is an increase in allergen-specific IgE antibodies, but the usual rise in IgE seen during natural seasonal exposure is blunted.² Over the course of several years, the amount of allergen-specific IgE declines, but it does not disappear. In keeping with this there is little effect on immediate skin test responses to allergen. In contrast, the late-phase skin test response is virtually abolished after successful SIT. Similar patterns are observed for late-phase nasal and airway responses.³

SIT also has clear effects on allergen-specific T cells (Fig. 93.1). Both in the skin and in the nose, successful SIT is accompanied by a reduction in

Table 93.1 Possible mechanisms of immunotherapy

Induction of specific immunoglobulin G (IgG) (blocking) antibodies
Reduction in specific IgE (long-term)
Reduced recruitment of effector cells
Altered T-cell cytokine balance (shift to Th1 from Th2)
T-cell anergy
Induction of regulatory T cells

Fig. 93.1 Possible mechanisms of successful specific immunotherapy. Specific allergen immunotherapy induces Th1 and T-regulatory cells, which have direct and indirect effects on immunoglobulin E (IgE) production, Th2 function, and the expression of allergic inflammation. IgG₄ production is stimulated via interleukin-10 (IL-10), although its significance in blocking allergic responses remains uncertain.

T-cell and eosinophil recruitment in response to allergen challenge. In parallel, there is a shift in the balance of Th1 and Th2 cytokine expression in the allergen-challenged site. Th2 cytokine expression is not affected, but an increased proportion of the recruited T cells express the Th1 cytokines IL-2, interferon-γ (IFN-γ), and IL-12.^{4,5} In addition there is induction of allergen-specific CD4 T-regulatory cells that express CD25, Fox p3, and IL-10.⁶ IL10 has a number of biologic effects that could explain the beneficial effects of immunotherapy. These include modulation of IL4-induced IgE production by B cells in favor of IgG₄, inhibition of IgE-dependent mast cell activation, inhibition of human eosinophil cytokine production and survival, suppression of IL5, and induction of antigen-specific anergy. Taken together, these findings suggest that SIT modulates allergen-specific T cells, which would tend to explain why the clinical and late-phase responses are attenuated without much effect on allergen-specific antibody levels. Further work in this area is now concentrated on finding more efficient ways of inducing allergen-specific T-regulatory cells.

SIT FOR ANAPHYLAXIS

Anaphylaxis to Hymenoptera venom is relatively rare, but can be fatal. Venom-specific IgE antibodies can be found in 30–40% of adults for a few months following a sting, but these usually disappear in a few months. Some individuals react more vigorously, with high concentrations of venom-specific antibodies, which may persist for many years without further exposure to stings. This group of patients are at risk of anaphylaxis to subsequent stings and a small number die from anaphylaxis each year. Estimates are hard to come by, but a figure of 10–20 deaths per year in the USA has been cited. This problem is distinct from deaths caused by so-called ‘killer bees,’ which are behaviorally inclined to cause multiple stings, and hence cause death by massive envenomation, without involvement of an allergic mechanism.

Before embarking on venom immunotherapy the patient needs to be carefully assessed and some account taken of the natural history of venom allergy.⁷ Patients who have experienced systemic symptoms after a sting are at much greater risk of anaphylaxis on subsequent stings, as compared to patients who have only had large local reactions. The frequency of systemic reactions to stings in children and adults with a history of large local reactions is about 5–10%, whereas the risk in patients with a previous systemic reaction is between 30 and 70%. In general, there is a lower risk of repeated systemic reactions in children, and in those with a history of milder reactions. The risk of systemic reaction to field stings in adults diminishes over 10–20 years towards 15–30% but does not seem to return to the background prevalence in the general population (3%). Children with a history of cutaneous systemic reactions had less than 5% risk of anaphylaxis during observation for 10–20 years. There is no test that accurately predicts the outcome of the next sting. Live sting challenges are a useful research tool but are not generally acceptable for use in clinical practice. Unfortunately, even if sting challenges are performed, they are not absolutely predictive, and patients who do not react to a first challenge sting may react to a subsequent sting.

In making a decision whether to recommend venom SIT, the physician should also take account of occupational and geographic factors that may affect the likelihood of future stings. Bee stings are much commoner in beekeepers, their families, and neighbors, whereas wasp stings tend to be sporadic, but are an occupational hazard for bakers, gardeners, outdoor caterers, and greengrocers. Other factors to be considered are the potential risks of emergency treatment with epinephrine and the various medical contraindications to SIT (see below).

Immunization with venom accelerates the process of risk reduction and confers rapid protection against both field and laboratory stings. There appears to remain a low risk of systemic reaction (10%) for many years after discontinuing venom immunotherapy. Although reactions to stings after therapy is stopped have rarely been severe, several fatalities have been reported in patients with other risk factors (mastocytosis, severe historical reactions, systemic reaction during venom SIT). In children, the chance of systemic reaction to a sting remains < 5% for up to 20 years after discontinuing venom SIT.

Desensitization with venom preparations provides protection against field and laboratory stings, although a minority of patients will still react despite completing their course of therapy. After completing venom SIT, there is a residual risk of systemic reactions of about 10%, but these are usually mild. Patients undergoing SIT for venom anaphylaxis should be offered injectable epinephrine and other anti-allergic medication for use in the event of a sting.

Table 93.2 Endpoints for trials of specific allergen immunotherapy (SIT) in asthma

Spirometry	Airflow obstruction determined by forced expiratory volume in 1 second, peak expiratory flow rate Bronchial irritability assessed with histamine/methacholine PC ₂₀ challenge (see text for details)
Symptoms	Wheeze, nocturnal waking, cough, breathlessness, time off work/school (diary cards or visual analogue scales)
Drug use	Bronchodilator use as surrogate for symptoms
Cost:benefit due to SIT	Reduction in other drugs, lost work, etc., compared to costs of SIT and time lost
Safety	Careful assessment of risk–benefit relationship
Immunology	Allergen-specific immunoglobulin G ₄ Skin test responses Nasal allergen challenge responses Inhalation allergen challenge responses

ASSESSING EFFECTIVENESS IN CLINICAL TRIALS OF SIT FOR ASTHMA AND RHINITIS

The two main keys to success in designing any clinical trial are the application of appropriate criteria for subject recruitment and the selection of appropriate clinical endpoints (Table 93.2). In allergic rhinitis efficacy is generally assessed in terms of symptom scores, recorded on a daily basis on a diary card or a personal organizer. Several symptom scales are in use, which all rely on a categorical grading system (e.g., 1 = mild, 2 = moderate, 3 = severe). These measures carry the implicit assumption that the step from 1 to 2 is equivalent to the step from 2 to 3 for the purposes of statistical analysis. By assigning numerical values to nonparametric variables, one may either overestimate or underestimate the true effects of therapy. Reduction in rescue medication use is also measured, as in theory patients may improve their symptoms because they use more medication. In practice most studies that show improved symptom scores show parallel reductions in medication usage, but some studies show reductions in medication usage without a statistically significant reduction in symptoms. Combining symptom and medication scores is fraught with difficulty. It is almost impossible to agree on equivalences between different drugs, let alone the relative value of one antihistamine tablet versus one day when symptoms are moderate rather than mild.

When assessing improvement in asthma, it is important to remember that most patients with atopic asthma have relatively mild disease that is usually easy to control with standard doses of conventional anti-asthma drugs. Cases of severe asthma are relatively few in number and the role of allergy in their disease is often less obvious than in mild cases. In mild cases, resting spirometry will usually be close to predicted values, so there is little scope for improvement in simple spirometric measures such as

forced expiratory volume in 1 second (FEV₁). Peak expiratory flow rates (PEFR) may show improvement, especially in the early-morning values, which are more likely to be reduced below the patient's best possible value than evening peak flow rates. Objective measures of bronchial irritability are more useful markers and a shift in the concentration of histamine or methacholine needed to induce a 20% fall in FEV₁ (PC₂₀) is commonly used. This measurement can be quite variable within individuals, so the minimum change that would be clinically significant is a change of at least one doubling dilution in the PC₂₀. Other bronchial challenge tests such as exercise challenge or adenosine inhalation may provide additional insights into the ability of an anti-asthma treatment to prevent acute attacks. Both these parameters depend indirectly on the PC₂₀, so again it is important to consider statistical and biological significance separately.

Although these challenge models are useful surrogates for evaluating anti-asthma treatment, more credence is placed on improvements in the symptoms or progression of the disease than on protection against laboratory challenges. Lately there has been a move to assess efficacy in terms of improvements in quality of life or as health gain per unit cost. These analyses are becoming increasingly sophisticated but require careful validation to ensure that the quality of life instrument is sensitive to the illness being studied and that the economic model is realistic.

Finally, many trials of SIT for asthma and rhinitis have studied laboratory surrogate markers such as changes in IgG subclasses, T-cell function, or skin test responses. Although such paraclinical measures do change during SIT, and can shed light on the mechanisms of successful SIT, they cannot be used to provide direct evidence of clinical efficacy. Studies that show antibody or T-cell changes without direct clinical evidence of efficacy neither support nor undermine the established evidence that SIT works, albeit in mysterious ways, to improve the symptoms of appropriately selected patients.

SIT FOR ALLERGIC RHINITIS

Allergic rhinitis is the main indication for SIT worldwide. As with all uses of SIT, it is important to select patients appropriately. The allergic basis of the rhinitis should be carefully assessed on history and skin or blood tests for IgE, while other relevant causes should be excluded. Tests of nasal sensitivity are not used in routine clinical practice but may be useful for assessing effectiveness in clinical trials.

The effectiveness of SIT in seasonal allergic rhinitis has been confirmed in many trials, using grass, ragweed, and birch pollen. Moreover, SIT has been shown to be clinically effective even in patients with severe seasonal rhinitis that is resistant to conventional drug therapy.⁸ In this trial, the largest double-blind placebo-controlled study of SIT to date, SIT was used to treat patients whose grass-pollen rhinitis was resistant to standard drug therapy. The active group showed a 30–40% decrease in symptoms and medication use in the first year of treatment, which was accompanied by reduced rescue medication usage. Although they were only treated with grass pollen, patients with multiple allergic sensitization responded at least as well as those who were monosensitized to grass pollen (Fig. 93.2). Limited data are available regarding the long-term efficacy of SIT for allergic rhinitis, but formal studies have shown that the effects last for at least 3 years after discontinuing therapy.⁹ Longer-term studies are difficult to conduct, but efficacy has been shown for up to 10 years in open studies. The benefits of SIT for perennial rhinitis are less well established than for seasonal rhinitis. In part this reflects the difficulty in determining the extent to which allergy is responsible for

Fig. 93.2 Effect of grass-pollen specific allergen immunotherapy on symptom scores and medication use in a clinical trial of 410 subjects. Polysensitized subjects responded at least as well as those who were monosensitized to grass pollen. (Data adapted from Frew AJ, Powell RM, Corrigan CJ, et al. Efficacy and safety of specific immunotherapy with SQ allergen extract in treatment-resistant seasonal allergic rhinoconjunctivitis. *J Allergy Clin Immunol* 2006; 117: 319–325.)

perennial symptoms. Allergy to housedust mite is common and does not always cause symptoms. Conversely, there are other causes of perennial rhinitis, including vasomotor instability, infection, and aspirin sensitivity. Nevertheless, clinical trials have shown a definite benefit provided the subjects are appropriately selected.¹⁰ Clearer evidence of efficacy has been obtained in rhinitis due to pet allergy. Several studies have shown a marked improvement in tolerance of cat exposure after SIT, confirmed both on challenge tests (Fig. 93.3) and in simulated natural exposure.¹¹

As with any therapy, the risks and cost-effectiveness of SIT need to be assessed on a case-by-case basis. Current drug therapy for rhinitis can be very effective, but about 60% of patients with seasonal allergic rhinitis report inadequate symptom control, even when taking maximal doses of antihistamines and intranasal glucocorticoids. Others experience nose bleeds from intranasal steroids and drowsiness from antihistamines. Moreover, we are now more aware of the adverse effects of rhinitis on quality of life. SIT offers a useful option for these patients as well as a logical approach to dealing with the underlying problem.

SIT FOR ASTHMA

Immunotherapy was widely used to treat allergic asthma in the UK prior to 1986 but evidence of severe adverse reactions, including a small number of fatalities, led to SIT being abandoned for asthma treatment in the UK, although asthma remains a common indication for SIT in North America and continental Europe.^{11, 12} There is no doubt that SIT is effective on asthma symptoms and protects against specific and nonspecific triggers. However, the role of allergic sensitization in ongoing asthma is less clear than for rhinitis, and the risks of therapy are undoubtedly greater in asthma. Current drug therapies for asthma aim to suppress the airways inflammation and smooth-muscle contraction that are characteristic features of asthma. None of these treatments are curative

and asthma rapidly recurs on ceasing treatment. Moreover, none of the current drug therapies is directed against agents that might cause asthma. Allergen avoidance has been proposed as a potentially useful maneuver in those with allergic asthma, but although asthma control can be improved by extreme forms of allergen avoidance (e.g., admission to hospital, sending children to holiday homes at altitude), there is little evidence that similar benefits can be achieved using the type of allergen avoidance that can be achieved in suburban homes. There is thus scope for improving asthma care and for identifying allergen-specific therapies. SIT offers the possibility of deviating the immune response away from the allergic pattern and towards a more protective or less damaging response.

The efficacy of SIT in adult asthma has been assessed in many trials over the last 50 years. The results of these studies have often been difficult to interpret, either because poor-quality allergen extracts were used or because of poor study design. Many trials were not placebo-controlled; they were either open or single-blind, and in most cases only small numbers of patients were treated. A recently updated meta-analysis identified 75 papers published between 1954 and 2001.¹³ Thirty-six of these were for mite allergy, 20 for pollen allergy, 10 for animal dander allergy, two for mold allergy, one for latex allergy, and six used combinations of allergens. Concealment of allocation was clearly adequate in only 15 trials. A wide variety of different measurements were made, which makes it difficult to reach a firm view on the overall effectiveness of SIT. Symptom scores improved in the treated groups – it was necessary to treat four patients to prevent one from exacerbating, and to treat five to prevent one from needing an increase in medication. SIT reduced the airways response to inhalation of specific allergen and also improved nonspecific bronchial reactivity.

The economics of using SIT to treat asthma are that some reduction can be achieved in anti-asthma drug costs, but these do not offset the costs of SIT. This means that the cost-benefit analysis depends greatly on the value placed on symptom reduction and perhaps the prevention of progression.

SIT reduces the early asthmatic response to inhaled allergen in cat-allergic asthmatics and attenuates responses to cat room exposure. Interestingly, these studies showed a clear delay in onset of symptoms and an overall reduction in symptoms and peak flow recordings after exposure to cats, but there was no protection against allergen-induced increases in nonspecific bronchial hyperresponsiveness. In contrast, SIT with a dog dander extract has not been shown to be effective in clinical trials.

Several double-blind placebo-controlled studies have examined the effects of SIT in asthmatic patients sensitive to housedust mite. Early studies showed conflicting results, but recent studies using more modern extracts have found beneficial effects on symptoms, anti-asthma drug use, and bronchial hyperresponsiveness.

COMPARISON OF SIT WITH OTHER THERAPIES

The majority of clinical trials of SIT for asthma have compared SIT either with untreated historical controls or with a matched placebo-treated group. To date, the effectiveness of SIT in asthma has rarely been compared with conventional management (avoidance measures and inhaled or oral anti-asthma drugs). One study assessed SIT in asthmatic children receiving conventional drug therapy and found no additional benefit in patients who were already receiving optimal drug therapy.¹⁴

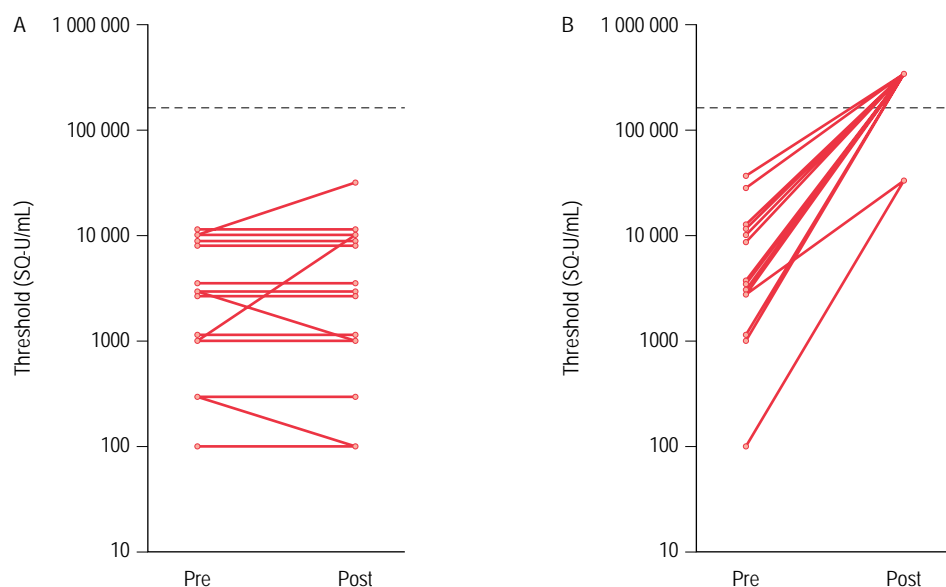

Fig. 93.3 Effect of specific allergen immunotherapy with cat dander extract on conjunctival provocation test threshold. (From Varney VA, Edwards J, Tabbah K, et al. Clinical efficacy of specific immunotherapy to cat dander: a double blind placebo controlled trial. *Clin Exp Allergy* 1997; 27: 860–867.)

There are some flaws in the design of this study and further work of this type is urgently needed.

EFFECTS OF SIT ON THE NATURAL HISTORY OF ALLERGIC DISEASE

A proportion of patients with allergic rhinitis go on to develop asthma each year. This annual rate of progression has been estimated at 5% in college students,¹⁵ but this is perhaps surprisingly an area of considerable ignorance. A number of long-term epidemiological studies are now in progress under the auspices of the International Study of Asthma and Allergies in Childhood (ISAAC) and these should eventually shed light on the rate of progression at different ages and the extent of regional and international variation. It has been suggested that SIT may modify the natural history of asthma in children who have allergic rhinitis but have not yet developed asthma. Only limited data are available to support this proposition. In the key study, a group of 205 children aged 6–14, without previously diagnosed asthma, were treated with SIT for birch or grass-pollen allergy in an open randomized design. Three years after completing treatment 45% of the untreated group had developed asthma whereas only 26% of the treated group had asthma. These results have been sustained to 7 years after completing therapy. Thus four children had to be treated to prevent one case of asthma, which makes this an extremely effective therapy.¹⁶ SIT may also modify the progression of established asthma. An early open study using uncharacterized mixed allergen extracts supported this view, with about 70% of treated children losing their asthma after 4 years' therapy, compared to about 19% of untreated controls, a result that was sustained up to the age of 16 years. The proportion of children whose asthma was severe at age 16 was also much lower in the treated group.¹² By modern standards, this study was not well designed, and it needs repeating with modern SIT extracts in an up-to-date trial design.

CLINICAL PEARLS

FACTORS ASSOCIATED WITH ADVERSE REACTIONS TO SPECIFIC ALLERGEN IMMUNOTHERAPY

- Dosage errors
- Asthma, especially uncontrolled/severe
- Highly sensitive patients
- Concurrent treatment with β -adrenergic blockers
- Accelerated regimens (rush, ultra-rush)
- Injections from new vials (especially with nonstandardized extracts)
- Injections during periods of exacerbation of symptoms
- Injections given during active viral or bacterial respiratory tract infections

SIT can also prevent the development of new sensitizations.¹⁰ In both open and double-blind studies, monosensitized children were much less likely to acquire new sensitivities, as shown by skin tests, than comparable control groups. It seems probable that this effect is indirect. In other words it is unlikely that SIT with housedust mite directly affects B cells that recognize cat or grass pollen, but by treating the housedust mite allergy, SIT may reduce inflammation in the nose, and hence modify the likelihood of exposure to other allergens proceeding to sensitization. There is as yet no evidence to support claims that SIT is different from drug therapy in terms of influencing the evolution of established asthma. In part this reflects the reluctance of physicians to

use SIT to treat severe asthma. Studies that have investigated withdrawal of therapy have found fairly rapid recurrence of asthma symptoms, although rhinitis symptoms seem to show much more sustained relief after SIT.

SAFETY

The main factor preventing the wider adoption of SIT is the risk of serious adverse reactions. In general, SIT is quite safe in patients who do not have asthma, but significant numbers of deaths have been reported in the UK and the USA when SIT has been used to treat patients whose asthma is unstable.¹⁷ The incidence of systemic reactions in patients receiving SIT for asthma varies between series and has been reported to range from 5% to 35%. In contrast, serious systemic reactions occur after about 1 in 500 injections in patients with rhinitis. Some adverse events are due to giving the wrong dose, emphasizing the need to check doses carefully before each injection. Others occur when patients change from one vial to another. Most allergists therefore cut back on the dose when changing vials to minimize this risk. Systemic reactions are much more likely if the patient has an intercurrent viral illness so doses should be delayed if the patient is unwell or has any signs of active asthma.

It is generally agreed that immunomodulatory treatments should not be used in patients with autoimmune disorders or malignant disease. Although there is no hard evidence that SIT is actually harmful in these groups, it seems unwise to attempt manipulation of the immune system in such patients, not least because of the risk that spontaneous and unrelated variations in the autoimmune disorder or cancer may be blamed on SIT. Other medical contraindications to SIT include significant coexistent cardiac disease, which may be exacerbated by any adverse reactions to SIT. Patients on β -adrenergic blockers should also not receive SIT. Although they are not at increased risk of adverse reactions, their physiological response to the cardiovascular component of anaphylaxis will be impaired, and they will not respond to the epinephrine that is used to treat adverse reactions to SIT.

CLINICAL PEARLS

CONTRAINDICATIONS TO SPECIFIC ALLERGEN IMMUNOTHERAPY (SIT)

Active autoimmune disease

Malignancy

Severe asthma/uncontrolled asthma

Pregnancy – do not start SIT, but it can be continued in a patient in whom treatment is well established

Patients taking regular:

β -adrenergic blockers

Angiotensin-converting enzyme inhibitors

Tricyclic antidepressants

ALTERNATIVE FORMS OF IMMUNOTHERAPY

Allergic disorders have attracted more than their fair share of attention from alternative medical practitioners. Alternative allergy practice covers three principal themes: (1) the use of unconventional diagnostic tests to seek causative agents for diseases that are known to be allergic in origin; (2) the use of unconventional therapies to treat allergic disease; and (3) the diagnosis and therapy of diseases that are not conventionally considered to involve allergic mechanisms.

Unconventional forms of immunotherapy include the use of topical immunotherapy, enzyme-potentiated desensitization (EPD), and homeopathic desensitization.

High-dose topical immunotherapy regimes were used in the first half of the 20th century, but then lost ground to injection immunotherapy in conventional medical practice. Over the past 15 years, there has been a resurgence of interest in sublingual immunotherapy (SLIT), which is based on the concept that allergens given via the mucosal surface are handled differently from allergens given by injection, leading to a form of immunological tolerance. It has been shown in animal models that IgE responses to allergens can be reduced or prevented by oral administration of allergen. The precise mechanisms by which this 'oral tolerance' is induced remain unclear, but it seems likely that the route of allergen processing and presentation is a critical determinant of the subsequent T-cell response. In mice, locally administered allergen is taken up by mucosal dendritic cells and then presented to T cells together with IL-12, biasing the response towards a Th1 profile and away from the pro-IgE Th2 profile. It is less clear whether this mechanism can suppress established allergic responses. In contrast to the animal models, the immunological response to SLIT in human studies has been relatively modest. Some changes have been found in skin sensitivity but most studies have not found any change in systemic parameters such as specific IgE, specific IgG, or T-cell cytokine balance.

Nevertheless, a body of evidence has accumulated from well-conducted clinical trials, indicating that SLIT can be effective, with up to 30–40% reductions in symptom scores and rescue medication usage in seasonal allergic rhinitis.¹⁸ Treatment regimes typically involve a rapid build-up phase followed by treatment about 3 times per week with rapidly dissolving tablets containing allergen extracts. Some preparations are supplied in liquid form, with a calibrated dropper. A recent meta-analysis of SLIT found 22 studies in which 979 patients received active therapy.¹⁸ Although many of these studies were small and inconclusive, the combined results indicate that SLIT is indeed effective, with an estimated power of about two-thirds that seen in comparable studies of injection SIT. Local side effects were common, but well tolerated. Systemic side effects were relatively rare, and none of the side effects were judged to be life-threatening. Only limited data are available in children. Other forms of topical immunotherapy (oral, nasal) seemed to be ineffective. SLIT is now being used routinely in some parts of Europe (especially Italy and France), but often the doses and regimes being prescribed are different from those used in the clinical trials. Overall SLIT is likely to widen the scope of SIT and bring in additional prescribers. As with all forms of immunotherapy, patient selection will be the key to ensuring that therapy is targeted to those who are likely to benefit from it.

ENZYME-POTENTIATED DESENSITIZATION

This form of SIT uses very small doses of allergens, given together with the enzyme β -glucuronidase. The allergen doses are approximately 0.1% of the doses used in conventional SIT and side effects are apparently not encountered. The theory behind EPD is that the β -glucuronidase enables the allergen to gain access to the immune system more efficiently than is possible with conventional SIT. No convincing evidence to support the efficacy of EPD has been presented, and a recent double-blind placebo-controlled trial was negative.¹⁹

HOMEOPATHIC DESENSITIZATION

A detailed discussion of the principles underlying homeopathy lies outside the scope of this chapter. However, homeopathy espouses the concept that diseases can be treated by very small doses of substances that cause similar symptoms. Some homeopathic remedies are mimics of the disorder, whereas others use the actual material that triggers the disorder. Thus, homeopathic remedies for hayfever bear some superficial similarity to SIT. A recent systematic review of homeopathy concluded that homeopathy did appear to offer some benefit, and cited trials of homeopathy in hayfever as an example of good practice.²⁰

FUTURE DIRECTIONS

Developments in molecular biology should lead to improvements in conventional SIT (Table 93.3). Possible avenues include the use of recombinant allergens, which would allow much better standardization of allergen vaccines, as well as some fine-tuning of vaccines for patients with unusual patterns of reactivity. Most allergic patients react to the same components of an allergen extract, the so-called major allergens, which are defined as those allergens recognized by over 50% of sera from a pool of patients with clinically significant allergy to the material in question. However, not all patients recognize all major allergens and some patients only recognize allergens that are not recognized by the majority of allergic patient sera. This latter group may not respond to standard extracts, but might be better treated with a combination of allergens to which they are sensitive. Until the advent of molecular cloning, this was impossible to achieve. The availability of recombinant allergens for SIT should thus lead to better characterization of the range of sensitivities, and ultimately to better vaccine products. Initial trials with cocktails of recombinant allergens have shown efficacy,²¹ but no commercial products are yet available.

Table 93.3 Possible new technologies for immunotherapy

Recombinant allergens
T-cell peptide vaccines
Th1 immunostimulants (e.g., mycobacteria, CpG)
Allergen-immunostimulant complexes
Anti-IgE
Adjuvants (e.g., monophosphoryl lipid)

Another alternative approach is to inject allergens directly into lymph nodes, under ultrasound guidance. Proponents of this approach argue that, after subcutaneous injection, less than 1% of the injected material reaches the lymphatic system, and therefore if it is the dose that reaches the lymph node that drives the benefit of SIT, then direct intranodal administration should be more efficient and also safer. Early studies with doses of about 1% of standard SIT have shown immunological efficacy, with some signs of clinical efficacy and reduced risks of side effects.²²

Since the epitopes recognized by IgE molecules are usually three-dimensional, whereas the epitopes recognized by T cells are short linear peptide fragments of the antigen, it should be possible to distort allergens or create peptide fragments that will modulate T cells without risking anaphylaxis. Several distinct approaches have been tested. Cross-linking allergen proteins with aldehydes reduces their ability to bind to IgE antibodies, without affecting their T-cell epitopes. Such allergoids have been shown to be effective in rhinitis due to grass pollen or house-dust mite.²³

Short peptide sequences can also be used as vaccines, which should not be recognized by IgE antibodies.²⁴ Peptide vaccines can either be natural sequences or altered peptide ligands. If high doses of natural peptides are given, these induce high-dose tolerance in T cells.²⁵ Altered peptide ligands induce anergy by providing an incomplete activation signal. Both approaches will be affected by the major histocompatibility complex type of the individual undergoing treatment. By sequential alteration of Der p peptides, it is possible to suppress proliferation of T-cell clones recognizing native Der p peptides, as well as suppressing their expression of CD40 ligand and their production of IL-4, IL-5, and IFN- γ . These anergic T cells do not provide B-cell help for isotype switching to IgE, and, importantly, this anergy cannot be reversed by providing exogenous IL-4. In humans, the main focus has been on cat allergen (Fel d1) peptides, which can reduce the level of symptoms on exposure to cat dander.²⁶ Similar work has also been reported with peptides of phospholipase A₂ (a major allergen in bee venom). However, to date peptide vaccines have not shown any greater efficacy than conventional vaccines.

Two new approaches using DNA vaccines are also undergoing serious consideration. The first of these is a general approach, using CpG oligodeoxynucleotides (ODN). This technology is essentially a refinement of vaccination adjuvant technology, since CpG ODN have been shown to be the principal activity from complete Freund's adjuvant. Pre-administration of CpG ODN prevented both airways eosinophilia and bronchial hyper-responsiveness in a mouse model of asthma and these effects were sustained for at least 6 weeks.²⁷ Experiments are also being conducted with CpG ODN coupled to ragweed allergen, which enhances immunogenicity in terms of eliciting a Th1-type response to ragweed allergen, but reduces its allergenicity.^{28, 29} A contrasting approach is to use allergen-specific naked DNA sequences as vaccines. This technology is still in its infancy, but preliminary data suggest that giving naked DNA leads to production of allergens from within the airways epithelial cells.^{30, 31} Due to the different handling pathways for endogenous and exogenous allergens, it seems that the endogenously produced allergen elicits a Th1-type response and, if this can be reproduced in allergic humans, it is hoped that this may overcome the existing Th2-pattern response and eliminate the allergy. However, the potential for generating a powerful Th1-type response to ubiquitous agents means that this approach will need careful evaluation in animal models before it can be pursued in humans.

The recent introduction of monoclonal antibodies directed against IgE offers another alternative. Treatment with anti-IgE reduces immediate and late-phase responses to inhaled allergen³² and should also reduce the risk of adverse effects from SIT injections. Moreover, when anti-IgE is combined with conventional SIT, the effects are additive against seasonal allergic rhinitis.³³ However, the high cost of anti-IgE and the need for regular infusions are likely to limit its use to patients with severe allergic disease that cannot be managed by other means.

CONCLUSIONS

SIT is established as a treatment for allergic rhinitis and for venom hypersensitivity, but is more controversial when used to treat allergic asthma. When used in appropriately selected patients, SIT is effective and acceptably safe, but care is needed to recognize and treat adverse reactions. Appropriate training of allergists and SIT clinic support staff is essential. Despite a century of use, the precise mechanisms of action of SIT remain uncertain. Current emphasis on the role of T-regulatory cells is leading to renewed attempts to simplify SIT regimes and reduce its risks. Future directions in SIT include the development of vaccines that are better standardized, and the use of recombinant allergens, both of which should improve the safety profile of SIT. In parallel, and perhaps in the longer term, we should look for the development of general immunomodulatory therapies, which would be particularly advantageous for those patients sensitized to multiple allergens.

Cytokine therapy

John W. Steinke, Gabor Illei, Gülbû Uzel,
JoAnn M. Mican

94

Cytokines serve as the critical soluble mediators of the immune response and as such are attractive potential therapeutic agents for a variety of disorders in which inflammation plays a central role. Among these are autoimmune and allergic diseases with excess inflammation that could potentially be modified by administering specific cytokines or combinations of cytokines. Alternatively, the clinical application of cytokine therapy in certain infectious diseases has already proven successful, demonstrating a potentially wider role of cytokines as adjunctive therapy in combination with conventional anti-microbials for specific infectious diseases, and raise the possibility that this form of therapy could also be useful in immunodeficiency disorders. This chapter will present the current status of cytokine therapy in autoimmune, allergic, infectious, and immunodeficiency diseases.

■ CYTOKINE THERAPY OF AUTOIMMUNE DISEASES ■

Cytokines mediate a wide variety of biological activities that are relevant to autoimmune diseases, including inflammation induced by an immune response, as well as tissue repair and remodeling. The roles of different cytokines in autoimmune diseases have been widely studied. It has become clear that excessive production of proinflammatory cytokines, as well as the relative paucity of regulatory cytokines contribute to the immunopathogenesis of these diseases. Restoring optimal cytokine balance may have therapeutic value that theoretically could be achieved either by blocking inflammatory cytokines or inducing or providing anti-inflammatory ones. To date, approved cytokine therapy in clinical practice is limited to the use of interferons. Other approaches, such as administering anti-inflammatory cytokines, have been disappointing. Cytokine blockade is considered in Chapter 95.

MULTIPLE SCLEROSIS

In multiple sclerosis (MS) activated autoreactive T cells, B cells, and other mononuclear cells cross the blood-brain barrier and enter the central nervous system (CNS). These mononuclear cell infiltrates, together

with resident CNS cells, can cause injury to oligodendrocytes and myelin. There are at least four clinical subtypes of this disease (Chapter 65). The relapsing-remitting form is the most common (80–85%) and is characterized by acute attacks (relapses) followed by remissions. Failure to recover from relapse is a major cause of disability but up to 30–50% of these patients accrue additional disability with subclinical relapses (secondary progressive phase MS). Human beta interferon (IFN- β) has been demonstrated to modulate many of these processes. Two forms of IFN- β are in clinical use: IFN- β_{1a} and IFN- β_{1b} . Despite some differences in their pharmacologic properties they have similar clinical effects. Seven large, randomized placebo-controlled trials have demonstrated clinical efficacy in both relapsing-remitting (three studies) MS and secondary progressive (four studies) MS.¹ These trials have consistently demonstrated that both forms of IFN- β reduce disease activity by reducing clinical attack rate and magnetic resonance imaging (MRI) activity measures. IFN- β treatment seems also to improve disease severity in MS; however these data are less convincing. The more recent clinical studies have focused on the impact of dose and optimal dosing frequency. The currently available data suggest that higher dose and/or more frequent administration may increase the efficacy of IFN- β treatment in MS.¹

The most common side effects of IFN- β are flu-like symptoms, headache, mild elevations in liver-associated enzymes, and anemia. Although depression is a possible adverse effect with interferon therapy, in these studies no significant relationship was observed with IFN- β .²

VASCULITIS

IFN- α (most commonly in combination with ribavirin) has been shown to be efficacious in hepatitis C-associated cryoglobulinemic vasculitis.³ Two recent studies showed encouraging results with pegylated interferon and ribavirin.^{4,5} IFN- α was also used as adjunct therapy in combination with corticosteroids and plasma exchange in a few patients with hepatitis B-associated polyarteritis nodosa.³ Based on reports of beneficial effects in patients with the hypereosinophilic syndrome (HES), IFN- α was used with encouraging results in a small number of patients with Churg-Strauss vasculitis refractory to conventional therapy.³

KEY CONCEPTS

CYTOKINE APPLICATIONS IN AUTOIMMUNE DISEASE

- >> Interferon- β (IFN- β) reduces relapses and progression of sustained clinical disability in patients with relapsing-remitting multiple sclerosis
- >> IFN- α is effective in hepatitis C-associated cryoglobulinemic vasculitis and Behçet's disease
- >> IFN- γ was not effective in scleroderma and did not improve lung function in idiopathic pulmonary fibrosis
- >> Initial clinical experience with interleukin-11 has been encouraging in Crohn's disease

Following a series of case reports, two controlled trials evaluated IFN- α in Behçet's disease (BD). In a placebo-controlled randomized double-blind study 15/23 IFN- α -treated patients responded compared to 3/21 placebo recipients. In another open-label nonrandomized study, 92% of the 50 patients with BD and posterior uveitis and/or retinal vasculitis responded to IFN- α .⁶

SJÖGREN'S SYNDROME

In several phase II studies low-dose natural human IFN- α administered by the oral mucosal route improved salivary output and decreased complaints of xerostomia in patients with primary Sjögren syndrome. In a phase III study, IFN- α increased unstimulated whole saliva flow significantly more than placebo, the co-primary endpoints of stimulated whole saliva flow and oral dryness were not significantly improved in the IFN- α group relative to placebo.⁷ Further studies are needed to establish the efficacy of IFN- α in Sjögren's syndrome.

FIBROSING DISEASES

IFN- γ , a potent inhibitor of collagen synthesis, was tested as a treatment for pulmonary fibrosis and systemic sclerosis. In a large randomized controlled trial IFN- γ did not improve lung function but there was a trend toward improved survival in the treated group.⁸ A follow-up trial is under way, with death as the primary endpoint. A randomized controlled trial of 44 patients with systemic sclerosis showed no significant benefit in improving skin thickness in the 27 treated patients compared to placebo.⁹ In spite of its significant antifibrotic effects, thus far the data suggest that IFN- γ alone is not likely to have a major impact on fibrosing autoimmune diseases.

INFLAMMATORY BOWEL DISEASE

Many autoimmune diseases, such as inflammatory bowel diseases and inflammatory arthritides, are characterized by local inflammation and a relative paucity of anti-inflammatory cytokines, such as interleukin-10 (IL-10) and IL-11, suggesting their possible therapeutic potential.

The encouraging results seen in early pilot studies of recombinant human IL-10 in Crohn's disease (Chapter 74) were not confirmed by

three large placebo-controlled trials.¹⁰ Similarly, the effect of IL-10 in rheumatoid and psoriatic arthritis was marginal at best and IL-10 is currently not being pursued as a therapeutic option.

In addition to its thrombocytopoietic effects, IL-11 has been shown to have anti-inflammatory effects. In a phase II study in patients with active Crohn's disease, IL-11 led to a 37% remission rate compared to 16% in the placebo group. In another study the long-term remission rate was similar (21%) in patients treated with recombinant human IL-11 or prednisolone.¹⁰

SUMMARY OF CYTOKINE THERAPY IN AUTOIMMUNE DISEASES

The success of interferon treatment in various diseases established the viability of cytokine therapy in autoimmune diseases. Further studies are needed to improve the modest clinical responses seen with other cytokines. Targeted delivery of cytokines to the site of inflammation or immune activation or the combination of various cytokines will enhance the specificity and efficacy of cytokine therapy.

CYTOKINE THERAPY IN ALLERGIC DISEASE

Cytokines and chemokines are important in the initiation and long-term maintenance of allergic disorders.¹¹ It has been suggested that the development of allergen-specific T cells with a Th2 cytokine profile (IL-4, -5, -9, and -13) plays a critical role in allergic rhinitis, asthma, atopic dermatitis, and hypereosinophilic disorders. Studies have focused on the effects of the Th2-derived cytokines and demonstrated that these cytokines mediate many of the pathological changes associated with these diseases. However, it has also been shown that proinflammatory cytokines (including tumor necrosis factor- α (TNF- α) and IFN- γ) are present in these diseases and can also mediate detrimental effects. While it is not as simple as tipping the balance from Th2 to Th1 cytokine expression, it is believed that by altering the levels of these proteins through antibody or cytokine treatment, the severity of disease can be alleviated.

ASTHMA

Asthma is not a single disease, but rather a complex disorder sharing the characteristics of reversible bronchial constriction, pulmonary inflammation and airway remodeling (Chapter 39). Current therapies include corticosteroids, leukotriene modifiers, and β -agonists that provide symptomatic control. None of these agents are able to provide long-term immunomodulation of the disease and reverse the observed pathological changes.

Given the understanding that asthma is characterized as a Th2-mediated disease, IL-4 was an obvious cytokine choice to target therapeutically (Fig. 94.1 and Table 94.1). To date, every anti-IL-4 therapy has failed during clinical evaluation, with the exception of human anti-IL-4 receptor antibody, which is still under preclinical development. All drugs were safe with no adverse reactions during treatment and there was no evidence of autoantibody production. The question is: why did the trials with these agents fail to show a significant improvement in asthma? Anti-IL-4 therapy is believed to involve immune deviation, resulting in a decrease in the number and activity of Th2 cells, so one concern is the

Fig. 94.1 Approaches to interleukin-4 (IL-4) signaling blockade. (A) IL-4 signaling. (B) IL-4 blockade utilizing soluble IL-4 receptor (sIL-4R). (C) IL-4 blockade utilizing anti-IL-4 receptor (IL-4R) antibody.

Table 94.1 Therapeutic agents with interleukin-4-inhibitory activity

Agent	Soluble human IL-4 receptor	IL-4 double mutein	IL-4/IL-13 trap	Humanized anti-IL-4 antibody	Human anti-IL-4 receptor antibody
Inhibition of IL-4	Yes	Yes	Yes	Yes	Yes
Inhibition of IL-13	No	Yes	Yes	Yes	Yes
Half-life	5 days	4–6 hours	5 days	18–21 days	18–21 days
Route of administration	Inhaled	Systemic	Systemic	Systemic	Systemic
Active in immune synapse	No	Yes	No	No	Yes

IL4 mutein – IL4 protein with two point mutations that has no agonist activity; IL4/IL13 trap-protein based drug candidate that binds IL4 and IL13 to prevent cell surface interaction.

choice of outcome measures and length of time employed used to document patient improvement. For soluble IL-4 receptor, the initial studies demonstrated a significant improvement in forced expiratory volume in 1 second (FEV₁) 2 hours after treatment, which is inconsistent with the agent acting through immune deviation.¹² A better measure would have been to investigate changes in antigen-specific T-cell populations and tissue and circulating eosinophil counts. It is possible that IL-4 is required to generate the Th2 cells important in asthma, but once formed, IL-13 plays a more important role in mediating the inflammatory responses associated with asthma. Since soluble IL-4 receptor and the humanized anti-IL-4 monoclonal antibody act by inhibiting IL-4 and not IL-13, they may not be effective in inhibiting responses in established asthmatics. Further clinical trials will clarify the target population of IL-4-based therapeutics for optimal inhibition of IL-4. Other disorders such as allergic rhinitis and atopic dermatitis are thought to be mediated by IL-4 and also represent areas for future investigation.

IL-5 is thought to be central to the development of eosinophilic inflammation as it is involved in the bone marrow maturation of eosinophil precursors, can act as a chemoattractant for eosinophils, and can induce eosinophil secretion.¹¹ Humanized monoclonal antibodies to IL-5 have been developed. This antibody was tested on asthmatics and found to reduce peripheral blood eosinophilia and inhibit eosinophil trafficking to the airway following allergen challenge.¹³ Unfortunately, treatment did not change the late asthmatic response or airway hyperresponsiveness upon histamine challenge.¹³ This may have been due to a loss of IL-5 receptor α expression on mature eosinophils and a greater dependence on IL-3 and granulocyte-macrophage colony-stimulating factor for eosinophil survival. A follow-up study demonstrated that, compared to placebo, individuals treated with anti-IL-5 displayed significantly reduced expression of the extracellular matrix proteins tenascin, lumican, and procollagen III in the bronchial basement membrane.¹⁴ Additionally, there was a reduction in transforming growth factor- β_1 (TGF- β_1) mRNA staining in airway eosinophils and TGF- β_1 protein in the bronchoalveolar lavage fluid. Further studies are needed to examine the activity of long-term use of anti-IL-5 in chronic asthma and the role that changes in remodeling have on lung function.

Anti-TNF- α is used in the treatment of rheumatoid arthritis. It has been reported that increased concentrations of TNF- α are found in bronchoalveolar lavage fluid of patients with severe asthma.¹⁵ This same study found that treatment with the recombinant soluble TNF- α receptor etanercept improved airway hyperresponsiveness; however this was an uncontrolled trial. A recent double-blind cross-over study demonstrated that, in a group of patients with refractory asthma, there were significant increases in the concentration of methacholine required to provoke a 20% decrease in FEV₁, an improvement in asthma quality-of-life scores and increased postbronchodilator FEV₁ following 10 weeks of treatment with etanercept as compared to placebo.¹⁶ Larger studies are needed to confirm this finding, but provide hope that there may be new treatment options available for this group of difficult-to-treat patients.

ATOPIC DERMATITIS

Atopic dermatitis is a skin disorder characterized by itching, scaling, and thickening of the skin, and is usually located on the face, elbows, knees, and arms (Chapter 44). This is usually the first manifestation of atopic disease and often occurs in infancy.

KEY CONCEPTS

CYTOKINE APPLICATIONS IN ALLERGIC DISEASE

- >> Anti-interleukin (IL)-4 and anti-IL-5 cytokine therapies have failed in primary clinical trials for asthma but further studies are required for a final decision to be reached
- >> Anti-tumor necrosis factor- α therapy shows promise as a treatment for refractory asthma
- >> Anti-IL-5 therapy shows promise in early clinical trials as a new therapeutic option in atopic dermatitis and hypereosinophilic syndromes

Early studies showed promise for treatment of atopic dermatitis with IFN- γ . Injection with recombinant IFN- γ resulted in significant improvements in physician and patient evaluations of clinical response, erythema and excoriation scores, and a trend towards less use of topical corticosteroids. However, no reductions have been reported in serum immunoglobulin E (IgE) or in allergen-specific IgE levels in any studies with IFN- γ . Use of this treatment has been tempered by the observation that early or acute lesions are associated with the presence of IL-4 and other Th-2 cytokines, but chronic lesions show increased expression of IFN- γ .¹⁷ IFN- γ expression induces chemokines such as CXCL9 and CXCL10, facilitating further recruitment of T cells to lesions. As such, IFN- γ therapy may be best suited for cases of acute atopic dermatitis.

As eosinophils are thought to play an important role in atopic dermatitis, anti-IL-5 therapy has been tested as a new treatment for this disease. A randomized placebo-controlled study was performed using a two-dose treatment, followed for 2 weeks in patients with moderate to severe atopic dermatitis.¹⁸ Peripheral blood eosinophil numbers were significantly reduced in the anti-IL-5 group compared to placebo. A modest improvement, as assessed by the Physician's Global Assessment of Improvement, was found in the treated group. Other measures failed to show significant improvements and it was concluded that, using that protocol, anti-IL-5 failed to improve atopic dermatitis. Longer studies with different dosing protocols are warranted before final conclusions can be reached concerning this approach.

HYPEREOSINOPHILIC SYNDROMES

HES are a collection of heterogeneous disorders characterized by peripheral eosinophilia and end-organ damage associated with eosinophilic infiltrations (Chapter 23). The primary treatment for these syndromes is high-dose corticosteroids, often with cytotoxic chemotherapy. Some patients respond to treatment with imatinib mesylate that targets an intracellular tyrosine kinase, but there remain a significant number of patients who fail to respond to current therapeutic options.

IFN- α_{2b} has been used to treat idiopathic HES in patients who are resistant to conventional treatment. At the lowest dose tested (1.5 MU/day), IFN- α_{2b} resulted in a 90% reduction in the circulating eosinophil count in 4 of 6 subjects and 5 of 6 when the dosage was increased. Two

subjects with severe mucosal ulcers, resistant to conventional treatment, had complete resolution of ulcers during therapy, with no recurrence once treatment was stopped. It has been found that a combination of IFN- α_{2b} and hydroxyurea allows tapering of IFN- α_{2b} dosage and provides better control than either agent alone.¹⁹

Another promising option, currently in clinical trials, is the use of anti-IL-5 therapy to treat HES. Early studies have shown that, as with asthma, anti-IL-5 results in significant and rapid decreases in peripheral eosinophil numbers.^{20, 21} More importantly, clinical symptoms and biomarkers either stabilized or improved during treatment. In two of the studies, some of the patients exhibited rebound eosinophilia along with a worsening of symptoms 5–8 weeks into treatment. This phenomenon was found to be mediated by a soluble factor, most likely IL-5. The mechanism of how this occurs is still unknown and the long-term consequences are currently under investigation.

■ CYTOKINE THERAPY IN INFECTIOUS DISEASES ■

HEPATITIS B

The hepatitis B virus (HBV), a hepadnavirus, is a small DNA virus that causes chronic infection in approximately 400 million people worldwide. In many of these individuals it leads to cirrhosis and hepatocellular carcinoma. Since its approval in 1981, the HBV vaccine has resulted in reductions in the prevalence of HBV infection, carrier state, and the incidence of HBV-associated hepatocellular carcinoma.²² In spite of this, there remain millions of chronically infected individuals who require treatment to decrease the progression to cirrhosis, hepatocellular carcinoma, and death.

Chronic HBV infection is characterized by ongoing viral replication, as evidenced by the presence of serum HBV DNA and usually hepatitis B e antigen. (HBeAg) The goal of therapy is to suppress viral replication and thus stop progression of liver injury.²² Remissions are diagnosed based on the loss of markers of active viral replication and sustained loss of markers results in biochemical, clinical, and histological remission.

IFN- α was the first agent found to have a beneficial effect on chronic HBV infection and received Food and Drug Administration (FDA) approval for this indication in 1992. A 4–6-month course of 5 or 10 million units (MU) given subcutaneously 3 times per week induces long-term remission in 25–40% of patients.²³ A meta-analysis of 15 randomized controlled trials revealed that 33% of patients treated with IFN- α lost HBeAg from the serum versus 12% of controls.²⁴ A long-term follow-up study of 103 patients treated with IFN- α revealed clearance of HBeAg was the strongest predictor of survival with 5-year survival without complications of 95% as compared to fewer than 50% in those patients who did not clear HBeAg.²⁵

The FDA recently approved the use of weekly pegylated (PEG) IFN- α_{2a} for the treatment of chronic hepatitis B. Approval was based on two studies showing that patients with either HBeAg-positive or HBeAg-negative chronic HBV had significantly higher rates of response, as evidenced by HBeAg and HBsAg seroconversion and HBV DNA suppression after 48 weeks of therapy with PEG IFN- α_{2a}

than with lamivudine.^{26, 27} Lamivudine is a nucleoside analogue with activity against both HBV and human immunodeficiency virus (HIV) infection. Currently there are several nucleos(t)ide analogues approved by the FDA for the treatment of chronic HBV, including lamivudine, adefovir dipivoxil, and entecavir and several other agents actively being tested. The approach to therapy is rapidly evolving. When PEG IFN- α_{2a} should be considered and if it should be used in combination with nucleos(t)ide analogues is a debated topic. For further discussion, refer to a recently updated treatment algorithm for the management of chronic HBV infection in the USA, written by a panel of hepatologists.²⁸

HEPATITIS C

Hepatitis C (HCV) infection is caused by a RNA virus which is a member of the Flaviviridae family. Worldwide it is estimated that 180 million persons are infected with HCV. Although the infection is often asymptomatic, approximately 80% of infected patients progress to chronic hepatitis, and 5–20% of those will develop cirrhosis, end-stage liver disease, and in some, liver cancer.^{28–30}

IFN- α was first shown to be effective in the treatment of chronic hepatitis C in the late 1980s, when several randomized studies were published demonstrating temporary remissions in approximately 40% of patients treated with a regimen of 2–3 million units of recombinant IFN- α three times weekly for 24 weeks.^{31, 32} Relapses were common, occurring in more than 50% of patients treated. In the late 1990s, several large multicenter, prospective controlled trials showed that the combination of IFN- α with ribavirin (a nucleoside analogue) provided higher sustained virologic responses (SVR) than IFN- α alone.^{33, 34} In addition the optimal duration of treatment was found to be determined by HCV genotype. For genotypes 2 and 3, two-thirds developed a SVR whether treated with a 24-week or a 48-week course of combination treatment. However for genotype 1, a 48-week course resulted in a 30% SVR as compared to 17% for those treated for only 24 weeks.

PEG IFN- α administered weekly was found to be as effective as three times a week IFN- α . The current standard of care for treatment of HCV infection, and based on the findings of randomized trials, is PEG IFN- α_{2a} or PEG IFN- α_{2b} administered weekly combined with ribavirin 800–1200 mg p.o. daily. PEG IFN- α and ribavirin resulted in higher rates of SVR than with IFN- α given by injection three times a week together with ribavirin or PEG IFN- α used alone.^{35, 36} A third study revealed that a treatment duration of 6 months is sufficient for persons infected with HCV genotypes 2 or 3, resulting in SVR of approximately 80%.³⁷ For genotype 1, 12 months of therapy is currently recommended, which achieves SVR in approximately 50% of those treated. In addition to HCV genotype 1, higher baseline HCV viral load, African-American race, HIV coinfection, and lower ribavirin doses are associated with lower SVR.

Although long-term follow-up is not available for the combination PEG IFN- α /ribavirin therapy, it has been found that the majority of patients who remain in remission at 6 months following IFN- α monotherapy continue to be HCV RNA-negative and show improvement in liver inflammation and fibrosis 10 years later.³⁸

Current treatment strategies being further evaluated include intensified IFN- α therapy during the first several weeks of therapy and low-dose IFN- α therapy following 1 year of combined therapy.

KEY CONCEPTS

CYTOKINE APPLICATIONS IN INFECTIOUS DISEASES

- >> Interferon- α (IFN- α) and pegylated IFN- α are both Food and Drug Administration (FDA)-approved in the treatment of chronic hepatitis B infection
- >> Weekly pegylated IFN- α and ribavirin result in the longest sustained viral response in chronic hepatitis C infection
- >> IFN therapy is effective for the treatment of condylomata acuminata and recurrent respiratory papillomatosis
- >> Interleukin-2 (IL-2) combined with antiretrovirals increases CD4 counts in human immunodeficiency virus (HIV) infection
- >> IFN- α is FDA-approved for the treatment of acquired immunodeficiency syndrome (AIDS)-associated Kaposi sarcoma
- >> Systemic IFN- γ or intralesional IL-2 may be useful in leprosy and leishmanial infections
- >> IFN- γ is useful in some patients with persistent nontuberculous mycobacterial infections

CONDYLOMATA ACUMINATA AND RECURRENT RESPIRATORY PAPILLOMATOSIS

Studies of IFN effectiveness in the treatment of diseases caused by papillomaviruses date back to 1974, when leukocyte IFN was injected into a patient's plantar warts, causing the warts to disappear and reappear upon discontinuation of the IFN injections.³⁹ Numerous studies have followed, demonstrating effectiveness of local injections of IFN- β in treating common warts,⁴⁰ subcutaneous injections of IFN- γ , or systemic IFN- α for treating condylomata acuminata and local injections of IFN- α for treating condylomata acuminata.⁴¹ However studies comparing IFN to other forms of local therapy, for example, cryotherapy or imiquimod, have not been done.⁴² IFN- α is FDA-approved for the treatment of condylomata acuminata.

Recurrent respiratory papillomatosis (RRP) is a disease that occurs primarily in children and is caused by human papillomaviruses. It is characterized by recurrent growth of benign papillomas throughout the respiratory tract. Treatment includes endoscopic laser excisions and surgery; however, papillomas often regrow, requiring further therapy. For those patients with aggressive RRP, IFN- α has been successfully used. In 1988, Leventhal et al. reported the results of a randomized, cross-over trial of IFN- α in 66 patients with juvenile-onset RRP.⁴³ During periods of drug administration there was a statistically significant improvement observed. Nine of 57 patients with assessable airway disease achieved complete remission while no patients achieved complete remission during 6 months of observation alone. However, as was seen in prior reports, the patients who discontinued drug therapy showed a significant regrowth of papillomas within 4 months.

A long-term follow-up of this study was published in 1991, revealing approximately a 40% complete remission and a 40% partial remission rate over a 5-year period.⁴⁴ Based on the results of this study it has been recommended that patients with RRP who require surgery every 2–3

months be given a 6-month trial of IFN- α . To date a clinical trial establishing the optimal dose and duration of treatment with IFN- α for RRP has not been published.

HUMAN IMMUNODEFICIENCY VIRUS

HIV infection results in a severe cellular immunodeficiency disease characterized by decreased CD4 T cells that results in the development of opportunistic infections and other complications (Chapter 38). Treatment of HIV-infected patients consists of anti-microbial prophylaxis and combination anti-retroviral therapy to suppress HIV replication. Although much success has been achieved with these therapies, complete suppression of viral replication is not possible with current anti-retroviral medications. One complementary treatment approach is the use of IL-2.

IL-2 is a T-cell-derived cytokine with many effects on the immune system, including activation, proliferation, and differentiation of T, B, and natural killer (NK) cells (Chapter 10). Early *in vitro* studies culturing peripheral blood mononuclear cells from patients with acquired immunodeficiency syndrome (AIDS) in IL-2 demonstrated improvement in immune function, including T-cell proliferative responses to antigen and mitogen, NK-cell activity, antigen-specific cytotoxic lymphocyte activity, and IFN- γ production.⁴⁵

In 1996, Kovacs et al. published a randomized controlled study of IL-2 therapy in HIV-infected patients in which 60 patients with CD4 cell counts above 200 cells/mm³ were randomized to receive either nucleoside analogue anti-retrovirals alone or in combination with six cycles of intravenous IL-2 administered every 2 months, for 5 days, starting at a dose of 18 million IU/day.⁴⁶ At the end of 12 months, the mean CD4 count increased from 428 ± 25 cells/mm³ at baseline to 916 ± 128 cells/mm³ in the IL-2 group, compared to a decrease in the mean CD4 count from 404 ± 29 cells/mm³ to 349 ± 41 cells/mm³ in the control group ($P < 0.001$) (Fig. 94.2). Numerous studies have since corroborated these findings, including studies using IL-2 administered subcutaneously, IL-2 therapy in individuals with CD4 counts of less than 350 cells/mm³, and IL-2 administration to individuals not receiving anti-retroviral drugs with CD4 counts of greater than 350 cells/mm³.^{47, 48}

Recent publications have provided insights into possible reasons for the increase in CD4 cells following IL-2 administration. *In vivo* labeling studies have demonstrated a preferential increase in survival of both naïve and central memory CD4 cells (with half-lives that can exceed 3 years) following IL-2 administration that is critical to the sustained expansion of the CD4 cells.⁴⁹ In addition, a unique subset of naïve CD4 cells, CD4/CD45RO/CD25 cells, has been described that is distinct from antigen-triggered cells and regulatory T cells, and may play a role in the maintenance of a state of low T-cell turnover and sustained expansion of the CD4 T-cell pool.⁵⁰

Whether these findings will translate into improved clinical outcomes in HIV-infected patients is still not known. Three international, multicenter, phase III clinical end-point trials, SILCAAT, ESPRIT, and STALWART, are currently under way to address this question. IL-2 is not an FDA-approved therapy for HIV-1 infection and should only be administered to individuals as part of clinical trials designed to elucidate further the role of IL-2 in the management of individuals who are infected with HIV.

Other cytokines, including IL-7 and IL-15, are important in the regulation of T-cell homeostasis. IL-7 is a cytokine that increases the proliferation and survival of T cells. A multicenter, randomized single-blind study of subcutaneous IL-7 versus placebo in HIV-1-infected patients is currently under way.

Fig. 94.2 CD4 count changes with rIL-2. Change in CD4 lymphocyte counts during a randomized trial of intravenously administered IL-2 and anti-retroviral drugs or antiretroviral drugs alone. (Modified from Kovacs JA, Vogel S, Albert JM, et al. Controlled trial of interleukin-2 infusions in patients infected with the human immunodeficiency virus. *N Engl J Med* 1996; 335: 1350.)

IFN- α , known to inhibit HIV-1 replication in cell culture, has been studied since the 1980s for the treatment of patients infected with HIV-1. Results of these studies have yielded variable results; however some did reveal significantly lower plasma HIV RNA levels in the groups randomized to receive IFN- α .⁴⁵ The decreases in HIV-1 RNA levels were modest at best and these studies were conducted prior to the availability of potent anti-retroviral therapy.

AIDS-ASSOCIATED KAPOSI'S SARCOMA

Kaposi sarcoma (KS) is a tumor of vascular origin, with four clinical variants including classic KS, endemic KS, immunosuppression-associated or transplantation-associated KS, and AIDS-associated KS. These variants have identical histologic features, but differ in the specific populations of patients affected, the sites involved, and the clinical course. In 1994, herpes virus-like DNA sequences were identified in tissues from patients with AIDS-associated KS.⁵¹ KS-associated herpesvirus (KSHV) or herpesvirus-8 (HHV-8) have since been identified in all variants of KS.

The AIDS-associated variant was one the first recognized manifestations of AIDS. In 1983, in an open-label study, IFN- α was found to be effective in the treatment of patients with KS.⁵² High doses of IFN- α are used and yielded dramatic tumor regression of lesions in the skin, lymph nodes, oral cavity, and gastrointestinal tract, with up to a 40% response rate seen. Numerous studies since have corroborated these findings, leading to the FDA approval of IFN- α for the treatment of AIDS-associated KS.

With the use of highly active anti-retroviral therapy (HAART) in the mid-1990s for HIV, it became clear that HAART was also an important component of AIDS-associated KS treatment.⁵³ Lower doses of IFN- α (1 MU/day) in combination with nucleoside analogue anti-retroviral

medications was shown to induce tumor regression. Currently trials of PEG IFN- α in combination with HAART are under way.

LEPROMATOUS LEPROSY

Nathan et al. first used IFN- γ in the treatment of lepromatous leprosy at a dose of 1–10 μ g/day injected directly into the cutaneous lesion daily for 3 days in addition to anti-microbials.⁵⁴ IFN- γ was shown to enhance granuloma formation and markers of local inflammation and to decrease cutaneous bacterial burden. Other small studies confirmed these findings and in long-term studies of IFN- γ , erythema nodosum leprosum (ENL), a toxic immune response leading to nerve damage, was a complicating phenomenon, but was readily suppressible with thalidomide. Sixty percent of patients treated with the combination of IFN- γ and anti-mycobacterial drugs developed ENL compared to 17% of those treated with anti-mycobacterial drugs alone.⁵⁵ It is not clear if this effect is related to long-term IFN- γ therapy; but if this is the case, it may limit the use of IFN- γ in this disease.

Low-dose IL-2, given intradermally, has been shown to reduce numbers of *Mycobacterium leprae* both at the injection site and at remote skin sites.⁵⁶ In addition, cutaneous infiltration of CD4 lymphocytes, monocytes, and Langerhans cells and increased levels of circulating antibody to *M. leprae* antigens were observed.⁵⁷

LEISHMANIAL INFECTIONS

Leishmaniasis is a protozoal infection caused by intracellular parasites of the *Leishmania* species. It has various clinical presentations, including localized cutaneous, mucocutaneous, and visceral forms (kala-azar), of

Fig. 94.3 Critical pathways in host defense against mycobacterial infection. Mycobacterial infection induces interleukin-12 (IL-12) production by monocytes, which stimulates T cells and natural killer (NK) cells to produce interferon- γ (IFN- γ). After binding to its cognate receptor, IFN- γ activates macrophages to produce tumor necrosis factor- α (TNF- α) and to kill intracellular mycobacteria by mechanisms not yet defined. IFN- γ also drives IL-12 production. AFB, acid-fast bacilli; NO, nitric oxide; IFN- γ R1, IFN- γ receptor 1; IFN- γ R2, IFN- γ receptor 2; IL-12R β 1 and IL-12R β 2, IL-12 receptor chains; TNF- α R, TNF- α receptors.

the disease. There are case reports of patients with refractory mucocutaneous leishmaniasis in whom the disease remitted when IFN- γ was combined with pentavalent antimony treatment. Addition of IFN- γ has also been demonstrated to decrease the duration of antimony compound treatment (10 versus 20 days) needed to treat the infection successfully. In visceral leishmaniasis, patient lymphocytes were unable to produce IL-2 and IFN- γ in response to leishmanial antigens,⁵⁸ leading to defective macrophage killing of the parasite. IFN- γ , when used in combination with the standard chemotherapeutic agents, appears to fill in this gap in the cellular response, while at the same time increasing the intracellular concentration of the therapeutic agents.

A single study of 3 patients with disseminated cutaneous leishmaniasis treated with intradermal IL-2 demonstrated findings similar to those reported in leprosy, including reduction in numbers of organisms in nodular lesions that were injected with IL-2 along with infiltration by CD4 T cells and plasma cells.⁵⁹

NONTUBERCULOUS MYCOBACTERIAL INFECTIONS

In 1994, Holland et al. reported that IFN- γ , when used in combination with conventional anti-mycobacterial therapy, could be useful in the treatment of refractory disseminated nontuberculous mycobacterial (NTM) infections.⁶⁰ This observation was supported by the identification of patients with defects in the IFN- γ /IL-12 pathway in the setting of disseminated NTM infections (Chapter 35). These defects include

IFN- γ receptor (IFN- γ R1 and IFN- γ R2), the IL-12 receptor β 1 (IL-12R β 1) and IL-12 p40, STAT-1, and NEMO, all of which are necessary elements for IFN- γ signaling or function.^{61, 62} In addition to these genetic defects, familial or sporadic cases with unknown molecular defects, patients with isolated CD4 lymphopenia, those with HIV infection or immunosuppression are predisposed to disseminated infections with NTM or bacillus Calmette-Guérin (BCG) and have been seen as candidates for cytokine therapy, primarily IFN- γ .

Following the phagocytosis of mycobacteria, macrophages release IL-12 and IL-18, which stimulates the production of IFN- γ by T and NK cells (Fig. 94.3). IFN- γ is a pleiotropic cytokine that binds to its receptor with high affinity, leading to receptor dimerization. IFN- γ signaling initiates the transcription of IFN- γ -regulated genes, some of which lead to cytotoxic T-cell activation (production of cytolytic proteins) and phagocyte activation (production of superoxide and nitric oxide, upregulation of Fc receptors and major histocompatibility complex (MHC) molecules, reduction in lysosomal pH).⁶³ IFN- γ also stimulates the production of IL-2, TNF- α , and other cytokines, that participate in the host defense against mycobacteria. Although the exact mechanism of how IFN- γ controls mycobacterial infection remains unclear, animal studies suggest a mycobacteriostatic effect, probably via acidification of mycobacteria loaded vesicles.⁶⁴ *In vitro* studies on the anti-mycobacterial effects of IFN- γ and human macrophages have produced conflicting data. However, a recent study suggests that Th1 effector function in chronic tuberculosis requires persistent IL-12 production,⁶⁵ which can be further driven by excess IFN- γ in the infected milieu.

Even though subcutaneous and aerosolized IFN- γ has been used in the treatment of disseminated and pulmonary NTM infection and in patients with multidrug-resistant tuberculosis, its real therapeutic value is unclear outside partial and dominant IFN- γ R1 or IL-12 pathway defects. Patients with unknown genetic defects and abnormal IL-12 and IFN- γ production or with idiopathic CD4 lymphocytopenia in the absence of HIV infection produce low levels of IFN- γ in response to phytohemagglutinin *in vitro*. In these patients, a combination of anti-mycobacterial agents and IFN- γ administered subcutaneously at a dose of 50 μ g/m² body surface area three times weekly may help clear the disseminated NTM infection while improving the overall clinical condition.^{60, 66} Side effects related to IFN- γ include low-grade fever, headache, and joint and muscle pain, all of which can be managed with oral acetaminophen prior to IFN- γ dosage. Relapse of infection is not uncommon upon discontinuation of treatment. This is probably due to the fact that the underlying problem related to IFN- γ regulation persists.

In complete IFN- γ R1 and IFN- γ R2 deficiencies, cells do not respond to IFN- γ , making IFN- γ therapy far less likely to be effective. In partial IFN- γ R1 deficiency, patients have an intermediate phenotype and treatment should include anti-microbials and subcutaneous IFN- γ .⁶⁷ Dominant negative IFN- γ R1 deficiency (AD IFN- γ R1) results in overexpression of mutant receptors that cannot transduce a signal. However, there is residual IFN- γ responsiveness such that adjunctive IFN- γ accentuates the effect of anti-mycobacterial agents and has been used successfully as a therapeutic approach. In IL-12p40 deficiency, lymphocytes secrete IFN- γ at a reduced level in the absence of functional IL-12, making IFN- γ and/or IL-12 potential therapeutic options. In IL-12R β 1 deficiency, mutations in IL-12R β 1 cause a lack of cell surface expression of this protein and patients usually respond to antibiotic therapy with resolution of infections. For those patients in whom cure is not complete with anti-microbials alone, a trial of IFN- γ therapy is warranted.

Naturally occurring neutralizing autoantibodies to IFN- γ have been described as an acquired defect, creating an unusual susceptibility to mycobacteria and leading to severe disseminated disease.⁶⁸ Since these patients have normal IFN- γ receptor expression and signaling, a trial of high-dose IFN- γ therapy along with other measures to block the autoantibody production (plasmapheresis, monoclonal agents targeting B cells) can be considered in addition to anti-mycobacterial agents.

Localized pulmonary disease secondary to NTM infection is a separate entity from the disseminated form. This is commonly seen in patients with underlying structural lung problems (i.e., bronchiectasis, cystic fibrosis, primary ciliary dyskinesia, smokers) or in elderly women with slight body habitus. The underlying predisposition at the genetic or cellular levels remains unknown. This cohort of patients is being studied for the systemic administration of IFN- γ . The best results with IFN- γ have been achieved in those with noncavitary lung disease (Holland SM, unpublished data). A recent but limited study of aerosolized IFN- γ (500 μ g of IFN- γ three times a week for 4 weeks) for cavitary pulmonary tuberculosis in HIV-infected and noninfected subjects reported clinical improvement and increased expression of IFN- γ inducible genes in bronchoalveolar lavage cells.⁶⁹

Studies of IFN- γ use in AIDS-related mycobacteremia infection are limited. It is clear that IFN- γ works as an adjuvant only in combination with anti-mycobacterials in this setting, resulting in a decline in mycobacteremia. IFN- γ effects were observed in the presence of low CD4 T-cell counts, suggesting some T-cell-independent effect.⁷⁰

TREATMENT OF IMMUNODEFICIENCY DISEASES

CHRONIC GRANULOMATOUS DISEASE

Chronic granulomatous disease (CGD) of childhood is an uncommon disease characterized by disorders of phagocyte oxidative metabolism resulting in recurrent infections caused by catalase-positive microorganisms and granuloma formation secondary to severe chronic inflammation (Chapter 21). In 1991, a randomized, double-blind, placebo-controlled study in 128 patients given IFN- γ 50 μ g/m² three times per week was shown to increase the time to first infection and decreased the number of serious infections by 67% in patients with CGD.⁷¹ In 2004, a study of 76 patients who received long-term IFN- γ reported it to be effective and well tolerated.⁷² Patients were followed up to 9 years (328 patient-years). The incidence of serious infections was 0.30 infections per patient-year and the mortality rate was 1.5% per patient-year. Adverse events were reported in 37% of patients, fever being the most common. IFN- γ was approved by the FDA for the prophylactic treatment of CGD in the USA in 1991.

COMMON VARIABLE IMMUNODEFICIENCY

Common variable immunodeficiency (CVI) is a heterogeneous syndrome characterized by hypogammaglobulinemia and recurrent bacterial infections (Chapter 34). Treatment of CVI involves aggressive treatment of infections with antibiotics and regular infusions of intravenous immunoglobulin. Many patients with CVI have abnormalities of T-cell activation and deficient secretion of cytokines, including IL-2. A patient who received open-label, weekly PEG IL-2 was found to have increased IgA and IgM levels, *in vitro* immunoglobulin secretion, lymphocyte proliferative responses, mononuclear cell production of IL-2 and IL6, and

KEY CONCEPTS

CYTOKINE APPLICATIONS IN IMMUNODEFICIENCY DISEASES

- >> Interferon- γ (IFN- γ) is Food and Drug Administration (FDA)-approved for treating chronic granulomatous disease based on decreased numbers of infections and hospitalizations in controlled trials
- >> Interleukin-2 therapy in common variable immunodeficiency has shown some promising *in vitro* effects but these must be confirmed with evidence of clinical improvement
- >> IFN- γ 1b is FDA-approved for the treatment of malignant osteopetrosis

clinical improvement.⁷³ In a placebo-controlled, double-blind, cross-over study of 10 patients, a significant reduction in severe infections was observed, but only in the 5 patients who received IL-2 the first 6 months. The decrease occurred not while receiving the IL-2 but during the next 6 months when they were receiving placebo⁷⁴ and no patients had a reversal in their disease. Whether IL-2 will be of clinical benefit in CVI patients is a question that needs further evaluation.⁷⁵

OSTEOPETROSIS

Congenital malignant osteopetrosis is a disease characterized by reduced leukocyte superoxide formation, an increased incidence of infections, and defective osteoclastic function with decreased bone reabsorption. Most children die within the first decade of life from severe infections, neurologic deficits, or bone marrow failure. Bone marrow transplantation is curative; however only about 40% of patients have a suitable donor.

With the success seen with IFN- γ treatment of patients with chronic granulomatous disease, IFN- γ 1.5 μ g/kg three times a week, was administered subcutaneously for 6 months to 8 patients with osteopetrosis.⁷⁶ A significant decrease in trabecular bone volume was observed, as well as an increase in hemoglobin concentration, platelet count, and leukocyte production of superoxide. A follow-up study of 14 patients treated with the same regimen for 18 months revealed findings similar to the prior study and additionally, in 6 patients for whom pretreatment data were available, a 96% decrease in the frequency of infections requiring antibiotic therapy was observed. Long-term IFN- γ therapy increases bone resorption and hematopoiesis and improves leukocyte function⁷⁷ and, in 2000, the FDA approved IFN- γ 1b for the treatment of malignant osteopetrosis.

SUMMARY

The data to date regarding cytokine therapy in a host of diseases associated with either too much inflammation or an inadequate immune response has been mixed. However, there are currently a number of approved uses for cytokine therapy in these settings and the list is likely to grow as ongoing studies are completed and new studies are designed. It is also seems clear that combinations of cytokines may prove to be more effective as therapeutic agents in certain disease types or categories, but to date combination therapy has not been actively investigated.

Monoclonal antibodies and fusion proteins

Susan J. Lee, Arthur F. Kavanaugh

95

The immune system is composed of a complex array of diverse immunocompetent cells and pro- and anti-inflammatory mediators that exist in complex networks. These components interact through cascades and positive- and negative-feedback circuits to maintain normal inflammation and immunity. In various autoimmune and allergic diseases, a foreign or autoantigen may upset this fine balance, leading to dysregulated inflammation and ultimately pathologic findings characteristic of a disease. In recent years, there has been tremendous progress delineating the specific components of the immune system that contribute to various aspects of normal immunity and to specific disease states. With progress in biotechnology, these components have become targets for more specific immunomodulatory therapies.

Traditionally, the treatment for most autoimmune diseases consisted largely of potent immunosuppressive agents. Although effective, treatment of autoimmune diseases with immunosuppressive agents rarely achieved the full extent of clinical response desired. This generated a substantial unmet therapeutic need. Moreover, because such drugs nonspecifically inhibited numerous parts of the immune response, treatment had the untoward effect of predisposing patients to generalized immunosuppression and significant toxicities such as infections. These considerations, in conjunction with the progress in biotechnology, provided the thrust for the development of a new class of therapeutic agents commonly called 'biologic agents.' Development in this area has been brisk, and in recent years more than two dozen therapeutic biologic agents have been approved by regulatory agents for use in the clinic. The two most common classes of biologic agents approved to date are monoclonal antibodies (mAb) and fusion proteins. The notable potential for these agents derives from their ability to inhibit targets, for example particular components of the immune system, with exquisite specificity. This has the potential both to optimize outcomes by more thorough modulation of specific parts of the dysregulated immune response as well as to minimize potential adverse events related to more broad methods of immunosuppression.

The mechanisms of action of mAb and fusion proteins are diverse. The simplest mechanism of action would be inhibition of the function of a target molecule, either soluble or cell surface, by binding to it, and thereby preventing ligation with its counter-receptor. The potential

targets are myriad, and include specific molecules on B cells, T cells, and other immunocompetent cells. Such targets would be those with effector functions key to the cells' role in the disease being treated. In addition, various soluble inflammatory mediators, such as cytokines, chemokines, complement proteins, enzymes, immunoglobulin molecules, or their surface receptors, can also be targeted. The effects of such inhibition derive most directly from the removal of a particular interaction, for example the blocking of an inflammatory cytokine from binding its cell surface receptor and thereby transducing a signal. Such inhibition may interfere with the normal function of the target molecule, such as binding of a cell surface adhesion molecule. Simple competitive inhibition of a key ligand/receptor pair could induce diverse downstream effects, as has been seen for the inhibitors of tumor necrosis factor- α (TNF). Alternatively, biologic agents may alter cell populations by binding a target on a specific cell, and then engaging effector functions such as activation of the complement cascade or antibody-dependent cellular cytotoxicity (ADCC). All mAbs and many fusion proteins have immunoglobulin G (IgG) Fc pieces as part of their construct. If such Fc pieces remain functional, then these effector mechanisms can be utilized if the binding characteristics of the target are appropriate. Because the regions of the Fc piece mediating the processes are distinct, biologic agents affecting either complement ligation or ADCC can be constructed. Cell depletion could also be induced by apoptosis related to ligation of an appropriate cell surface target. Relevant targets for cell-depleting therapy would include lineage-specific molecules or activation molecules.

■ MONOCLONAL ANTIBODIES ■

MAbs to human targets are generated most readily in other species, for example in mice. Although murine mAbs can be effective, and several have been brought to the clinic as therapeutic agents, they are suboptimal for most indications. Being foreign, these relatively large protein molecules are immunogenic. The development of antibodies to the treating agent can potentially result in several undesirable consequences, such as a decrease in half-life due to more rapid elimination, and interference with the intended therapeutic function. Moreover, the

development of antibodies to the treating agent can directly cause severe allergic reactions, such as anaphylaxis. For these reasons, there has been great interest in developing mAbs that are composed of less foreign material (Fig. 95.1). With chimeric mAb, the variable region of a murine-derived mAb is fused through genetic engineering with the Fc piece of a human IgG molecule. The resulting construct is approximately one-quarter murine and three-quarters human origin. For humanized mAb, only the complementarity-determining regions (CDR) from the original murine mAb are retained, resulting in a construct that is approximately 95% human. There are a number of theoretical approaches towards creating human mAb to human targets, including immunizing human/severe combined immunodeficient (SCID) mouse chimeras, or using Epstein-Barr virus-transformed human B cells. One of the most commonly employed has been repertoire cloning. In this procedure, target antigen is used to capture human CDR generated from vast human cDNA libraries, with the mAb then constructed to incorporate the generated CDR.

The standard nomenclature for mAbs makes note of their source as the last four or five letters of the mAb name: -omab, murine; -ximab, chimeric; -zumab, humanized; -umab, fully human. The middle part of the name refers to the disease indication for which the mAb is intended: thus, '-lim-' for immune and inflammatory diseases, '-cir-' for cardiovascular disorders, and '-tu-' for tumors or neoplastic conditions. The first three or four letters are chosen by the sponsor/developer. In general, the more human the construct, the less immunogenic the mAb. Therefore, human mAb are less immunogenic than humanized mAb, which in turn are less immunogenic than chimeric mAb. As the consequences of antibodies developing to the treating mAb include not only decreased efficacy but also potentially adverse reactions, less immunogenicity is desirable. However, there are several caveats that should be noted. Even small molecules whose amino acid sequence is identical to human, such as recombinant insulin, can be immunogenic. In the case of mAb, even fully human mAb have certain potential differences from native Ig, such as patterns of glycosylation. In addition, although mAb with greater murine components are more immunogenic, much of the reactivity appears to be

idiotypic. Thus, patients who develop antibodies after treatment with one chimeric mAb might not be expected to demonstrate reactivity to another chimeric mAb. Also, other key factors that are relevant to the immunogenicity of a compound include those factors long known to affect the outcome of an immune challenge, including: route of administration (intravenous versus subcutaneous), treatment paradigm (continuous versus intermittent), and concurrent immunosuppressive therapy. In clinical practice, these factors have proven to be relevant considerations for the therapeutic use of mAb. While numerous mAbs have been approved by the US Food and Drug Administration (FDA) and other regulatory agencies, this chapter will focus on several key mAbs used in the treatment of allergic and autoimmune conditions: omalizumab, natalizumab, infliximab, adalimumab, rituximab, and efalizumab (Table 95.1).

FUSION RECEPTORS

Fusion proteins are typically composed of the extracellular domains of native transmembrane proteins, such as cell surface receptors, linked to another molecule. In most cases, the linker that has been used has been the Fc portion of human Ig, which achieves the desired effect of enhancing the pharmacokinetic properties of the construct. The Fc portion of the fusion receptor can be maintained to be functional and bind to complement and to cell surface Fc receptors. This allows effector function, and has been used for the compounds etanercept and alefacept. Alternatively, the construct can be engineered such that the Fc piece is unable to execute effector functions, as in the case of abatacept, which does not activate complement. As their primary mechanism of action, fusion receptors competitively inhibit the binding of a ligand to its specific receptor and thereby prevent downstream effects, such as activation of inflammatory cascade. However, ligation of certain molecules by fusion receptors may induce other functions as well. In this chapter, the focus will be on several important fusion receptors that have been brought to the clinic for autoimmune diseases: etanercept, abatacept, and alefacept (Table 95.1).

AGENTS THAT INHIBIT PROINFLAMMATORY CYTOKINES

Cytokines are small proteins that regulate diverse aspects of the function of the immune system and the inflammatory response. Individual cytokines often exhibit multiple effects and their activities are often synergistic with, or antagonistic to, the actions of other cytokines. Cytokines and inflammatory cells exist in a complex network where they interact through cascades of stimulation and inhibition. In a susceptible patient, an imbalance in the cytokine cascade can help the initiation and propagation of the immune-driven inflammation characteristic of autoimmune diseases. For example, in inflammatory arthritides such as rheumatoid arthritis (RA), psoriatic arthritis (PsA), and ankylosing spondylitis (AS), the important proinflammatory cytokines TNF- α and interleukin-1 (IL-1) have been shown to play a central role in disease pathogenesis and sustenance. TNF in particular appears to play a central role in inflammatory reactions, and has proven to be an especially attractive target for biologic agents. Among its sundry proinflammatory and immune-regulating activities, TNF activates various cell types, promotes accumulation of immunocompetent cells at sites of inflammation by activation of the vascular endothelium and upregulation of adhesion molecules, stimulates synthesis of other proinflammatory cytokines (e.g., IL-1, IL-6, granulocyte-macrophage

Fig. 95.1 Monoclonal antibodies.

Table 95.1 Food and Drug Administration-approved therapeutic biologics^a

Drugs	Description	Indications
Abciximab	Chimeric monoclonal Fab fragment to platelet IIb/IIIa	Acute MI; post-PTCA
Adalimumab	Human mAb to TNF- α	RA, PsA
Agalsidase beta	Recombinant human α -galactosidase A enzyme	Fabry disease
Aldesleukin	Recombinant IL-2	Metastatic renal cell cancer
Alefacept	Recombinant LFA-3/IgG Fc construct	Psoriasis
Alentuzumab	Humanized mAb to CD52	Chronic lymphocytic leukemia
Alteplase	Recombinant tPA	Acute MI, massive PE
Anakinra	Recombinant IL-1R antagonist	RA
Anti-thymocyte globulin (ATG)	Horse anti-human T-cell Ig	Acute renal transplant rejection, aplastic anemia
Basiliximab	Chimeric mAb to IL-2R	Acute renal transplant rejection
Becaplermin	Recombinant human PDGF gel	Diabetic ulcer
Bevacizumab	Humanized mAb to VEGF	Metastatic colorectal cancer
Cetuximab	Chimeric mAb to EGFR	Metastatic cancer
Daclizumab	Humanized mAb to IL-2R	Acute renal transplant rejection
Darbepoetin alpha	Recombinant erythropoietin	Anemia related to chemotherapy
Denileukin diftitox	Recombinant diphtheria toxin/IL-2 construct	Cutaneous T-cell lymphoma
Digoxin immune Fab	Fab against digoxin	Digoxin toxicity
Drotrecogin alfa	Recombinant activated protein C	Severe sepsis
Efalizumab	Humanized mAb to LFA-1 (CD11a)	Psoriasis
Etanercept	Recombinant soluble TNF-R/IgG Fc construct	RA, JIA, PsA, AS, psoriasis
Filgrastim	Recombinant G-CSF	Neutropenia
Galsulfase (rhASB)	Recombinant <i>N</i> -acetylgalactosamine 4-sulfatase	Mucopolysaccharidosis VI
Gemtuzumab ozogamicin	Humanized mAb to CD33	Acute myelocytic leukemia
Ibritumomab	Murine mAb to CD20	NHL
Infliximab	Chimeric mAb to TNF- α	RA, Crohn's, UC, PsA, AS
IFN- α (2a, 2b, etc)	Recombinant IFN- α	Hepatitis C, hairy cell leukemia, Kaposi sarcoma, hepatitis B, condyloma, melanoma, NHL
IFN- β (1a,1b)	Recombinant IFN- β	Multiple sclerosis
IFN- γ	Recombinant IFN- γ	Chronic granulomatous disease, osteopetrosis
Laronidase	Recombinant human α_1 -iduronidase	Mucopolysaccharidosis I
Natalizumab	Humanized mAb to $\alpha_4\beta_1$ integrin	Multiple sclerosis
Omalizumab	Humanized mAb to IgE	Severe allergic asthma

^aAccessed 4/06: modified from www.fda.gov/cder/biologics and www.drugs.com.

AS, ankylosing spondylitis; EGFR, epidermal growth factor receptor; Fab, fragment, antigen-binding; Fc, fragment, crystallizable; G-CSF, granulocyte colony-stimulating factor; HER, human epidermal growth factor receptor 2; IFN, interferon; IgE, G, immunoglobulin E, G; IL-2, interleukin-2; JIA, juvenile idiopathic arthritis; LFA, leukocyte function antigen; mAb, monoclonal antibody; MI, myocardial infarction; NHL, non-Hodgkin's lymphoma; PDGF, platelet-derived growth factor; PE, pulmonary embolism; PsA, psoriatic arthritis; PTCA, percutaneous transluminal coronary angiogram; RA, rheumatoid arthritis; RSV, respiratory syncytial virus; TNF, tumor necrosis factor; tPA, tissue plasminogen activator; UC, ulcerative colitis; VEGF, vascular endothelial growth factor

Continued

Table 95.1 Food and Drug Administration approved therapeutic biologics^a—cont'd

Drugs	Description	Indications
Oprelvekin	Recombinant IL-11	Thrombocytopenia
Palivizumab	Humanized mAb to RSV	Severe RSV
Rasburicase	Recombinant uricase	Post-chemotherapy hyperuricemia
Retepase	Recombinant tPA	Acute MI
Rituximab	Chimeric mAb to CD20	NHL, RA
Tenecteplase	Recombinant tPA	Acute MI
Tositumomab	Murine mAb to CD20	NHL refractory to rituximab
Trastuzumab	Humanized mAb to HER-2	Metastatic breast cancer

KEY CONCEPTS

THE ROLE OF TUMOR NECROSIS FACTOR (TNF) INHIBITORS IN CROHN'S DISEASE

- >> Treatment with monoclonal antibodies has been effective both as single therapy and as maintenance therapy
- >> Combination therapy with immunomodulators appears to enhance efficacy and minimize immunogenicity
- >> At doses studied to date, etanercept has not been effective in Crohn's disease, whereas anti-TNF monoclonal antibodies available have been effective
- >> Treatment with TNF inhibitor monoclonal antibodies also appears to be effective in ulcerative colitis

colony-stimulating factor), chemokines (e.g., IL-8), and other inflammatory mediators. IL-1, another inflammatory cytokine, also stimulates production of other proinflammatory cytokines, angiogenic factors, and endothelial adhesion molecules. Both TNF and IL-1 activate macrophages to release mediators destructive to bone and cartilage, including matrix metalloproteinases such as collagenase and prostaglandins.

TNF INHIBITORS

As of 2006, more than 1 million people worldwide have received one of the three currently available TNF inhibitors: (1) infliximab, a chimeric monoclonal anti-TNF- α antibody initially approved in 1998 for Crohn's disease; (2) etanercept, a recombinant soluble p75 TNF-receptor (CD120b)-IgG Fc fusion protein initially approved in 1998 for RA; and (3) adalimumab, a human monoclonal anti-TNF- α antibody initially approved in 2002 for RA (Table 95.2).

The conditions for which patients have most commonly received TNF inhibitors are RA and Crohn's disease. In Crohn's disease, there has been an evolution in the manner in which TNF inhibitors have been utilized.

Initially, treatment was for the most severe, refractory disease, and treatment was given as a single course. Following upon the successes achieved in this group of patients, repeated treatments and more chronic dosing regimens have been assessed. Also, the efficacy of TNF inhibitor therapy in another form of inflammatory bowel disease, ulcerative colitis (UC), has also been explored. To date, although the mAb TNF inhibitors have been effective in inflammatory bowel disease, the fusion protein construct has not been.

In RA, the effects of TNF inhibitor therapy have been dramatic. Initially, these agents were tested in patients with the most severe and active disease that had been refractory to all other available treatments. In this population, the TNF inhibitors not only substantially improved the signs and symptoms of disease, but also resulted in significantly improved functional status and enhanced quality of life. Most notably, treatment with TNF inhibitors was capable of attenuating the progression of joint damage as assessed radiographically, a characteristic of RA previously considered to be inexorable despite any form of therapy. Following upon the experience in refractory RA, the TNF inhibitors have also been tested in patients with earlier onset of disease. In early RA, the same breadth of positive responses that had been noted for more established RA was seen; however, the extent of clinical responses was even greater in these patients. The clinical success achieved by the TNF inhibitors in RA has been so dramatic that the introduction of this therapeutic approach has resulted in an alteration in the treatment paradigm for RA, with the goals of therapy being set higher than they had been prior to their introduction.

In addition to RA, other types of arthritis have also responded to treatment with TNF inhibitors. PsA, a form of inflammatory arthritis associated with skin psoriasis, often has clinical resemblance to RA. It is sometimes classified as one of the spondyloarthropathies, as a subset of patients has spinal involvement. As was observed in RA, treatment of PsA patients with the TNF inhibitors improved not only the signs and symptoms of arthritis, but also functional status and quality of life as well. In addition, prevention of the progression of radiographic joint damage was also demonstrated. Moreover, dramatic improvements in skin psoriasis were achieved, as were improvements in extra-articular involvement characteristic of PsA, such as dactylitis and enthesitis. Improvement in skin psoriasis with TNF inhibitor therapy has likewise been noted in patients without arthritis. In AS, although previously available therapies had the potential for some clinical improvement

Table 95.2 Characteristics of biologics: dosing, half-life, and indications

Agent	Dosing	Mode of delivery	Half-life
Cytokine inhibitors			
Etanercept	RA: 25 mg biweekly or 50 mg weekly JIA: 0.4 mg/kg biweekly	SQ	4–5 days
Infliximab	3–10 mg/kg every 4–8 weeks	IV	8–9.5 days
Adalimumab	40 mg every week–every other week	SQ	12–14 days
Anakinra	100 mg qd	SQ	4–6 hours
B-cell modulators			
Rituximab	NHL: 375 mg/m ² weekly × 4 doses RA: 500–1000 mg every 2 weeks × 2 doses	IV	60–170 hours
T-cell modulators			
Abatacept	RA: 10 mg/kg then every 4 weeks	IV	14.7 days
Alefacept	15 mg IM weekly × 12 weeks (can be repeated after 12-week observation period)	IM	270 hours
Adhesion-cell modulators			
Efalizumab	1–2 mg/kg weekly × 12 weeks	SQ	3–5 days
Natalizumab	300 mg every 4 weeks	IV	11 days
Immunoglobulin inhibitor			
Omalizumab	0.016 mg/kg IgE (IU/ml)/month divided every 2–4 weeks	SQ	26 days

IM, intramuscular; IgE, immunoglobulin E; JIA, juvenile arthritis; NHL, non-Hodgkin's lymphoma; RA, rheumatoid arthritis.

in peripheral arthritis, no therapy was effective at alleviating spinal inflammation. Therefore, the ability of the TNF inhibitors to improve spinal inflammation, both in terms of signs and symptoms as well as with imaging, such as magnetic resonance imaging (MRI), is all the more notable. While the success of TNF inhibitors in these autoimmune conditions has been remarkable, it is worth noting that, almost uniformly, treatment failed to induce long-term treatment-free remission or immunological tolerance. Thus, maintenance of clinical response requires continuous therapy.

TNF inhibitors have not proven effective in several other conditions, including several wherein there was pathophysiologic evidence for a role for this cytokine in the disease process. Among autoimmune conditions, TNF inhibitor therapy has been notably ineffective to date in several forms of vasculitis, including Wegener's granulomatosis and polymyalgia rheumatica/temporal arteritis. This is perhaps surprising, given the role of TNF in granuloma formation and maintenance. Also, in Sjögren's syndrome, therapy was not effective. In congestive heart failure (CHF), data from animal models implicated TNF as a key

mediator of deteriorating cardiac function, and hence an attractive target. However, TNF inhibitors have failed to improve patients with CHF in clinical trials, and sometimes resulted in worsened clinical outcome. Although they were limited, studies of TNF inhibitors that had negative results in multiple sclerosis, along with anecdotal reports of the development or worsening of demyelinating symptoms among RA patients treated with these agents, would seem to preclude further development of these agents in that condition. TNF inhibitors are still being actively investigated in a variety of other diseases, including Behçet's disease, uveitis, asthma, dermatomyositis/polymyositis, and others.

As regards safety, in general, TNF inhibitors have been well tolerated in clinical trials. *In vitro* evidence from studies assessing various aspects of immune function among patients receiving treatment with TNF inhibitors has suggested that TNF inhibitors do not cause broad immune system suppression. It appears that these agents selectively decrease proinflammatory cytokines while preserving both the humoral and cell-mediated arms of the immune response. In longer-term follow-up

KEY CONCEPTS**THE ROLE OF TUMOR NECROSIS FACTOR (TNF) INHIBITORS IN RHEUMATOID ARTHRITIS**

- >> Inhibition of a single cytokine can be highly effective
- >> Substantial improvement seen in signs and symptoms of disease, functional status, and quality of life
- >> Treatment can inhibit progression of joint damage, as assessed radiographically
- >> Most patients require continuous treatment for efficacy
- >> Long-term treatment-free remission is rare
- >> Switching from one TNF inhibitor to another TNF inhibitor can be effective
- >> Treatment with a TNF inhibitor plus methotrexate appears to have additive or synergistic efficacy, particularly as regards joint damage
- >> Combination therapy of a TNF inhibitor and methotrexate represents the current 'gold standard' for the treatment of rheumatoid arthritis

KEY CONCEPTS**THE ROLE OF TUMOR NECROSIS FACTOR (TNF) INHIBITORS IN ANKYLOSING SPONDYLITIS (AS), PSORIASIS, AND PSORIATIC ARTHRITIS (PsA)**

- >> In AS, treatment improves signs and symptoms of axial arthritis, peripheral arthritis, and extra-articular involvement, such as uveitis
- >> In AS, treatment appears to attenuate spinal inflammation, as assessed with magnetic resonance imaging
- >> In psoriasis and PsA, treatment improves signs and symptoms of disease, functional status, and quality of life
- >> In PsA, improvement has been noted in peripheral arthritis, dactylitis, enthesitis, and skin psoriasis
- >> In PsA, treatment can result in attenuation in the progression of joint damage, as assessed radiographically

studies of patients from clinical trials, and, more importantly, in postmarketing pharmacovigilance assessments, a number of relevant safety issues regarding the use of TNF inhibitors have emerged.¹ Adverse events associated with TNF inhibitors may be broadly classified as target/class-related or agent-related (Table 95.3).

Target-related adverse effects include those potentially attributable to the immunosuppression inherent in blocking a key component of the immune system such as an inflammatory cytokine. This would include the sequelae of impaired immunosurveillance, such as an increased susceptibility to infections and malignancies. Safety data from clinical trials have shown a small but consistent increase in infections among treated patients, although generally the risk of serious infections was not substantially greater, perhaps related to the close follow-up patients receive in clinical

CLINICAL PEARLS**LENGTH OF TREATMENT WITH TUMOR NECROSIS FACTOR (TNF) INHIBITORS**

- >> Almost uniformly, treatment with TNF inhibitors fails to induce long-term treatment-free remission or immunological tolerance. Thus, maintenance of clinical response requires continuous therapy

CLINICAL PEARLS**LACK OF EFFECT OF TUMOR NECROSIS FACTOR (TNF) INHIBITORS**

- >> TNF inhibitors have been shown to be ineffective in patients with congestive heart failure, multiple sclerosis, Wegener's granulomatosis, Sjögren's syndrome, temporal arteritis, and polymyalgia rheumatica

trials. As will be discussed below, the risk of infection with TNF inhibitor therapy has been shown to be substantially increased when combined with other biologic agents. For example, combination therapy with the TNF inhibitor etanercept and the IL-1 receptor antagonist anakinra resulted in a higher rate of serious infections in RA patients, despite the failure to achieve any additive clinical benefit. Data, particularly from pharmacovigilance, have noted a number of opportunistic infections (e.g., *Pneumocystis jirovecii* pneumonia, listeriosis, coccidioidomycosis) among those patients treated with TNF inhibitors. Interpretation of the excess risk of infections attributable to therapeutic intervention in RA needs to take into account the increased baseline risk of infections among RA patients. Thus, without a control group, it is sometimes difficult to ascertain the excess infection risk specifically attributable to TNF inhibitors in RA.

Another potential sequela of immunosuppression is malignancy. With a few notable exceptions, the bulk of the data to date do not support an increased risk of solid tumors related to TNF inhibitor therapy. However, greater numbers of hematological malignancies, particularly non-Hodgkin's lymphoma, have been observed. Like the problem with infections, complicating the assessment of the risk attributable to therapy is the increased baseline risk of lymphoma among RA patients. This risk, which seems to vary directly with disease activity and severity, would be expected then to introduce bias towards observing cases among patients treated with TNF inhibitors as the most severe and active RA patients are often the most common type of patients treated. However, if the observed increase related entirely to the subset of patients treated, one might anticipate that in years to come the incidence of lymphoma should decrease, as disease activity is diminished in such patients. Obviously this is an area of great interest and further long-term data are needed. In conditions being treated with TNF inhibitors, the relative impact of dose and duration of therapy and host factors such as comorbidities, relevant genetic polymorphisms, and concomitant medications on the risk of infections and malignancy remain incompletely defined. For example, patients with early RA, AS, or PsA tend to

Table 95.3 Safety issues with tumor necrosis factor inhibitors

	Target-related	Agent-related
Definite		Injection site reactions, infusion reactions, immunogenicity (e.g., serum sickness, anaphylaxis)
Probable	Infections, serious infections opportunistic infections (e.g. coccidioidomycosis), tuberculosis autoantibodies, lupus-like syndromes, hepatotoxicity	
Possible	Malignancies (lymphoma), demyelinating disorders (multiple sclerosis), hematologic abnormalities, congestive heart failure	

be younger and have fewer comorbidities than patients with long-standing RA, and would therefore be expected to have a lower incidence of certain adverse effects such as infection. The extent to which this may be true is still being investigated.

In addition to those adverse effects noted above, which might be associated with various immunomodulatory approaches, inhibition of TNF may predispose patients to a variety of untoward effects that seem to be specific to inhibition of the TNF molecule. These include an increased susceptibility to tuberculosis (TB), autoantibody production, hepatotoxicity, the development of demyelinating disease such as multiple sclerosis, and clinical worsening of CHF. Regarding TB, there is a fair amount of animal and *ex vivo* data supporting the important role played by TNF in controlling this infectious agent. Although few cases of TB were seen in early clinical trials, a number of cases were noted, including fatalities, soon after the more widespread use of TNF inhibitors, particularly in geographic locations where TB was endemic. Many cases were initially missed due to atypical presentations. In contrast to typical presentation of acute TB as pneumonia, about half of the cases of TB related to TNF inhibitors presented as extrapulmonary or disseminated TB. The majority of these TB cases appear to be reactivation of latent TB, with infection occurring within the first few months of therapy; however, newly acquired cases have been well described. The incidence of cases may be greater with the mAb TNF inhibitors than with the fusion protein inhibitor. Fortunately, screening for latent TB before initiating TNF inhibitor therapy has been an effective strategy, with a reduction in incidence of new TB cases by approximately 85%.

Treatment with TNF inhibitors has also been associated with development of autoantibodies. Although the mechanism of this is unknown, it does not appear to result from general immunosuppression, but rather to an aspect of TNF itself, perhaps induction of apoptosis. The autoantibodies typically generated include the generic antinuclear antibody (ANA, which develops in about half of RA patients treated with TNF inhibitors), antibodies to double-stranded DNA (anti-dsDNA, which develops in approximately 10–15% of patients treated with TNF inhibitors), and anticardiolipin antibodies. The clinical implications of these autoantibodies remain to be defined, as progression to a lupus-like illness appears to be uncommon.

THERAPEUTIC PRINCIPLES

ADVERSE EFFECTS OF BIOLOGIC AGENTS

- >> Adverse effects can be globally considered to be agent-related or target-related
- >> Target-related effects derive from inhibition of the target; for immunomodulatory therapies, this often includes immunosuppression and its potential sequelae (e.g., infection)
- >> Agent-related adverse effects relate to the specific agent; they may be mechanistic (e.g., cell lysis) or idiosyncratic (e.g., immunogenicity)

Agent-related adverse effects such as allergic reactions and antigenicity are idiosyncratic reactions that relate to the particular agent used. Antibodies to TNF inhibitor construct have been noted, with the highest rates being noted for the chimeric antibody infliximab. However, antibodies to adalimumab and etanercept have also been observed. As noted above, intermittent use and use without concomitant immunosuppressants have been associated with a greater propensity for the development of antibodies to TNF inhibitor. The extent to which these antibodies influence response rates or the duration of response to treatment remains to be fully defined.

Despite their shared ability to inhibit TNF, there are some notable differences between the three currently approved TNF inhibitors. Infliximab and adalimumab are IgG₁ mAb that are specific for TNF- α ; etanercept is a fusion protein of the type II TNF receptor, that therefore binds both TNF- α and lymphotoxin- α (previously known as TNF- β). The clinical relevance of this distinction is unknown. In addition, the binding characteristics of the mAb and the fusion protein differ slightly. While all agents bind soluble TNF with high affinity, the mAb have slightly higher affinity for membrane-bound TNF than the soluble TNF receptor, presumably related to the physical constraints of the binding domains of the soluble TNF receptor. Whether these differences may account for variability in efficacy (e.g., in Crohn's disease) or as regards any particular adverse effects remains to be seen.

INFLIXIMAB

Infliximab, a chimeric IgG₁ mAb specific for TNF- α , has been proven effective in RA.²⁻⁴ Initially in patients with well-established severe yet active disease, infliximab was shown to improve the signs and symptoms of RA, functional status, and quality of life. In early studies, it was demonstrated that the combination therapy with infliximab and methotrexate (MTX), a traditional disease-modifying anti-rheumatic drug (DMARD) used for RA, was synergistic. Part of this may relate to pharmacokinetic effects; concomitant treatment with MTX increases the area under the curve for infliximab concentrations by about 25%. Since these earlier studies, almost all studies of infliximab in RA patients have used it in conjunction with MTX. In addition to its use in established RA, infliximab was also tested in patients with early RA, defined as less than 3 years of disease. In early RA, even higher levels of response were noted with the combination of infliximab and MTX. In addition to the beneficial effect on signs and symptoms, the most notable result from the studies of infliximab in RA has been its ability to arrest in radiographic progression. This is quite distinct from, and superior to, results among patients receiving traditional DMARDs. In the trial of patients with early RA, while most patients on MTX monotherapy had a progression of radiographic damage, approximately 90% of patients on the combination therapy had no radiographic progression.⁴ Interestingly, inhibition of radiographic progression of disease seemed to be dissociated from clinical efficacy as measured by the typically utilized composite scoring measures, such as the American College of Rheumatology 20% improvement criteria (ACR 20). Thus, some patients who did not achieve an ACR 20 response still experienced inhibition of damage on X-ray.³ Although some of this dissociation probably relates to the inexactness of the ACR 20 in capturing the entire spectrum of clinical benefit, it does raise the possibility that distinct outcomes in RA may relate to different immunological process.

Infliximab has been shown to improve signs and symptoms of disease in patients with AS.^{5,6} Because MTX is not a standard therapy for spinal involvement in AS, infliximab monotherapy has been used in this condition. While the majority of outcome measures utilized in clinical trials focus on spinal inflammation, improvement with infliximab therapy has also been observed in peripheral arthritis, as well as in some extra-articular manifestations of disease such as uveitis. Interestingly, those with elevated acute-phase reactants at study entry, as well as those with evidence for spinal inflammation on MRI, tended to respond more favorably to TNF inhibitors. Paralleling data from RA, infliximab provided rapid clinical improvement, often as early as 2 weeks. Also, continued treatment was necessary to sustain the response, and all patients flared within a few months of discontinuing therapy. The ultimate goal in treating AS would be to stop the progression of spinal ankylosis. However, structural effects of TNF inhibitors or any drug on axial disease are difficult to assess due to the slow rate of skeletal progression in AS. In fact, such studies could probably not currently be done, as the amount of time necessary to see a meaningful difference in radiographic change between treatment and control would far exceed the time span considered ethical given the dramatic effect of TNF inhibitor therapy on the signs and symptoms of disease. Therefore, it is quite encouraging that TNF inhibitors have been shown to attenuate spinal inflammation on a sensitive imaging modality such as MRI.⁷

The treatment of patients with PsA requires consideration of the various potential areas of disease involvement, including peripheral arthritis, axial arthritis, skin and nail involvement, dactylitis, and

enthesitis. Similar to RA, the level of TNF- α is notably increased in biopsy samples of skin and synovial tissues from patients with PsA, providing rationale for TNF inhibitors in the treatment of PsA and psoriasis. All three currently approved TNF inhibitors have been associated with improvements in signs and symptoms of peripheral arthritis, dactylitis, and enthesitis associated with PsA as well as functional status and quality of life.⁸⁻¹¹ For all three agents, studies have allowed, but not required, patients to be on concomitant MTX. In all studies, the use of concomitant MTX has not seemed to affect any outcomes; however, given the study design, this does not address the important issue of whether there is synergy between the agents in PsA or psoriasis. In addition to improving the signs and symptoms of peripheral arthritis, treatment of PsA patients with TNF inhibitors also attenuated the progression of radiographic damage. As regards skin manifestations, all three TNF inhibitors induced clinical improvement. Interestingly, while the extent of improvement in peripheral arthritis was comparable among TNF inhibitors, the extent of improvement in skin psoriasis appears to be greater with the mAbs than with the soluble receptor construct. Whether this difference relates to differential mechanisms, dosages used, or some other factor remains to be defined. Preliminary analysis of individual patient responses shows that there may be a discordance between dermatologic and articular outcomes in individual patients, suggesting potential heterogeneity to pathophysiologic mechanisms underlying different clinical manifestations.

The levels of TNF- α are increased in the mucosa of inflamed intestine and thought to exert deleterious effects relevant to the pathophysiology of inflammatory bowel disease (Crohn's disease and UC). Infliximab has been shown to improve both clinical and endoscopic luminal fistulas and bowel mucosal inflammation associated with Crohn's disease.¹²⁻¹⁴ In Crohn's disease, the use of infliximab in combination with immunosuppressives (e.g., MTX, azathioprine), enhances efficacy and decreases immunogenicity. More recently, infliximab has been approved for the treatment of UC after promising results from two large phase III studies. Approximately 65% of patients receiving infliximab in addition to conventional therapy had a clinical response, with less rectal bleeding, compared to 31-35% in the placebo group.¹⁵

ETANERCEPT

Etanercept has been shown to improve signs and symptoms of arthritis rapidly and retard radiographic progression in both early and established RA.¹⁶⁻¹⁹ In long-term extension studies, many patients on etanercept were also able to decrease the doses of their concomitant MTX and/or corticosteroids. Although etanercept has been proven to be effective as monotherapy, and although there is no pharmacokinetic interaction, combination therapy with MTX appears to provide additional benefits. Thus, patients on combination therapy had the greatest radiographic protection compared to those on either etanercept or MTX alone.¹⁹

Etanercept is the only TNF inhibitor currently approved for the treatment of juvenile idiopathic arthritis (JIA). In a long-term follow-up study of more than 60 children with MTX-resistant polyarticular juvenile RA, etanercept provided sustained clinical improvement without an increase in the incidence of adverse effects.²⁰ Studies are ongoing to assess the efficacy and safety of infliximab and adalimumab in JIA.

Etanercept has been shown to improve signs and symptoms of arthritis and quality of life in patients with AS.²¹ In AS, the characteristics and the degree of clinical and radiographic response appeared comparable

among all three TNF inhibitors. As noted above, because MTX is not an effective therapy for spinal inflammation in AS, it has not been utilized in studies of the TNF inhibitors. Whether there may be any synergistic effect of the combination of TNF inhibitor and MTX on radiographic progression in AS remains to be seen. Etanercept has also been shown effective in improving the signs and symptoms of arthritis and quality of life in patients with PsA.⁹

ADALIMUMAB

Adalimumab has also been shown to improve signs and symptoms of arthritis and quality of life, and to retard radiographic progression in both early and established RA.^{22–24} Similar to etanercept, adalimumab can be given as monotherapy or in combination with MTX. However, the combination therapy has been associated with greater clinical response and radiographic inhibition than either adalimumab or MTX alone.^{22–24} Similar to infliximab and etanercept, adalimumab has also been effective in improving signs and symptoms of arthritis and functional status in AS patients, and in psoriasis and PsA. Adalimumab has also shown promising results in decreasing fistulas and bowel inflammation associated with Crohn's disease.²⁵

INTERLEUKIN-1 RECEPTOR ANTAGONIST

IL-1 is synthesized as an inactive precursor. Upon cleavage by IL-1 β -converting enzyme, it activates a variety of cells that can then release mediators destructive to bone and cartilage. In the RA synovium, although there is an increase in the naturally occurring IL-1 receptor antagonist (IL-1Ra) that prevents the binding of IL-1 to its receptor, IL-1R, the levels are apparently insufficient to counteract the effects of IL-1. Anakinra, approved in 2001 for the treatment of RA, is a recombinant competitive IL-1Ra that differs from the endogenous antagonists by a single amino acid addition at the amino-terminus. Compared to the TNF inhibitors, the clinical responses achieved by anakinra are modest; combined with cost and the need for daily injections, this has led to its relatively infrequent use in the treatment of RA. However, it has been gaining renewed interest in the treatment of treatment of familial cold autoinflammatory syndrome and Muckle-Wells syndrome, with promising results. These autosomal dominant disorders are characterized by mutated cryopyrin genes resulting in increased IL-1 activity. Similar to TNF inhibitors, anakinra can also modulate normal immune responses and potentially lead to adverse effects such as infections. In clinical studies, the overall rate of serious infections and malignancies has been comparable between the treated and the control groups. The most commonly reported infections were pneumonias, occurring more frequently in patients with underlying asthma, and cellulitis. However, as noted above, the combination of TNF inhibitor and IL-1Ra did lead to a higher incidence of serious infections. Because there was also no clinical benefit achieved with such an approach, this combination is not recommended for clinical use.¹

AGENTS THAT INHIBIT T CELLS

There is a large body of evidence suggesting autoreactive T cells, especially CD4 Th1 T cells, serve a key role orchestrating the immune-driven inflammatory responses in autoimmune diseases such as RA,

Crohn's disease, PsA, and psoriasis. Early attempts at eliminating CD4 cells with anti-CD4 mAb achieved a biologic effect, with reduction in circulating cells, but did not achieve a beneficial clinical effect. This may have been related to several factors, including insufficient effect at the tissue level, preferential targeting of naïve rather than memory T cells, deleterious effects on regulatory T cells, or others. Further attempts at manipulating T-cell function have utilized different approaches.

Productive CD4 T-cell responses require two signals (Chapter 13). The first signal comes from the binding of specific antigen appropriately presented in the context of major histocompatibility complex class II molecule to the T-cell receptor complex. The second signal comes from co-stimulatory molecules. If T cells fail to receive the second signal, then tolerance or ignorance of the antigen ensues, and a productive immune response is not generated. Co-stimulation can occur through several pairs of cell surface molecules on antigen-presenting cells (APCs) and T cells. Among the most important molecules is CD28, which binds CD80 and CD86. CD28 and its natural inhibitor, cytotoxic T-lymphocyte-associated antigen 4 (CTLA-4; CD152) are present on T cells and bind to CD80 and CD86 on APCs. CD28 ligation results in stimulation of T cells while CTLA-4 serves an inhibitory role. CTLA-4, which binds CD80 and CD86 with substantially higher affinity than CD28, inhibits the stimulatory effects of CD28 by competitively binding to CD80 and CD86.²⁶

ABATACEPT

Abatacept (CTLA-4 Ig) is a soluble chimeric human protein consisting of the extracellular domain of CTLA-4 (CD152) and the Fc portion of a human IgG₁ (Table 95.2). Abatacept has been developed in an attempt to downregulate T-cell responses and induce T-cell anergy by preventing CD28-mediated T-cell co-stimulation. Abatacept was approved for the treatment of refractory RA in 2005. It has been shown to be effective both in RA patients who had active disease despite concomitant MTX, and also in patients who had failed therapy with one or more TNF inhibitors.^{26, 27} Because of the larger clinical experience to date with TNF inhibitors, it is likely that it may be used initially in the clinic in patients who have previously tried TNF inhibitor therapy. Abatacept therapy has also been shown to attenuate the progression of radiographic damage in RA patients, and to improve functional status and quality of life. Treatment, which is given as a 30-minute intravenous infusion monthly, is generally very well tolerated.

Recently, a safety study assessed the combination of abatacept and TNF inhibitor therapy. In that study, a higher incidence of serious adverse effects, including infections, was seen at 1-year follow-up in the patients receiving combination therapy compared to those on monotherapy.²⁸ Although clinical efficacy was not rigorously tested in that study, at present the combination of these agents is not recommended in routine clinical use.

ALEFACEPT

The interaction of LFA-3 on APCs and CD2 on T cells is thought to be important in T-cell activation and in the development of cells into memory T cells. Alefacept is a fusion protein of a soluble form of the extracellular domain of LFA-3 attached to the Fc portion of an IgG₁ molecule. Alefacept was approved in 2003 for the treatment of chronic plaque psoriasis. It binds and depletes CD2⁺ T cells, utilizing cell-based

effector mechanisms via its Fc portion. Other cells also bear CD2 receptors, including natural killer cells and some bone marrow B cells, although the effects on these cells are less pronounced than on circulating memory T cells. Although the exact mechanism of action of alefacept is unknown, it is thought to improve psoriasis by inducing memory T-cell apoptosis, inhibiting inflammatory gene expression, and preventing T-cell migration into psoriatic plaques.²⁹ Alefacept, either as monotherapy or in combination with MTX, has been shown to be effective for skin psoriasis. T-cell depletion related to therapy did not correlate nor predict the response rate during treatment or follow-up. Despite its ability to produce a long-lasting depletion of memory T cells and lymphopenia, alefacept has been well tolerated without an increase in adverse effects, including infections and malignancies. Furthermore, both primary and secondary antibody response to neoantigen and memory response to recall antigen appeared to be intact.²⁹ Studies are ongoing to assess the long-term safety of repeated and/or combination therapy as well as its use in other autoimmune diseases.

■ IL-2 RECEPTOR INHIBITORS ■

Daclizumab is a humanized IgG₁ mAb, and basiliximab is a chimeric IgG₁ mAb. Both are directed against the IL-2 receptor on the surface of activated T lymphocytes. Both mAb bind to IL-2 receptors and prevent IL-2-mediated activation of lymphocyte in response to antigenic challenges. They are approved for the prevention of acute kidney transplant rejection and are used in combination with other immunosuppressive agents, such as cyclosporine and corticosteroids. Despite their potential to induce severe immunosuppression, IL-2 receptor inhibitors have overall been well tolerated.³⁰

■ AGENTS THAT INHIBIT B CELLS ■

Recent data suggest that B cells may contribute significantly to the initiation and perpetuation of the immune response in various autoimmune diseases. Not only can B cells produce potentially pathologic autoantibodies (e.g., rheumatoid factor, ANA) and proinflammatory cytokines, but they can also present antigens to T cells and provide co-stimulatory signals essential for T-cell activation, clonal expansion, and effector function.

Rituximab is a chimeric monoclonal IgG₁ antibody directed against B-lymphocyte surface antigen, CD20. It is thought to induce B-cell lysis by several mechanisms, including complement activation, ADCC, and induction of apoptosis. CD20 is restricted to the surface of pre-B and activated mature B cells. Within 24–48 hours of infusion, rituximab markedly depletes peripheral B cells (CD19⁺, CD20⁺). This effect can last up to 9 months after a single course of therapy. Despite its actions on B cells, the overall levels of serum Ig generally remain stable during treatment.³¹ However, some patients may exhibit an impaired humoral immune response with less robust B-cell proliferation to simple haptens and recall antigen challenge, presumably related to depletion of memory B cells with rituximab.

Rituximab was initially approved in 1997 for the treatment of relapsed or refractory low-grade or follicular CD20-positive B-cell non-Hodgkin's lymphoma. In 2006 its indication was expanded to include RA that had been refractory to TNF inhibitor therapy. In early studies, it was shown that rituximab combined with MTX or with cyclophosphamide was

more effective than as monotherapy.³² Later studies used this combination in patients who were naïve to or refractory to TNF inhibitor therapy.^{32–34} Rituximab has also been suggested to be effective in other autoimmune diseases such as systemic lupus erythematosus, primary Sjögren's syndrome, idiopathic thrombocytopenic purpura, chronic inflammatory demyelinating polyneuropathy, and vasculitis. Additional trials are under way that should answer questions regarding dosing, treatment intervals, safety, and tolerability in these conditions. Despite the potential for immunodeficiency related to depletion of mature B cells, no significant increases in infections, either serious or opportunistic, were reported in both RA and non-Hodgkin's lymphoma patients treated with rituximab.³⁵ This could be related to preserved function of plasma cells, which lack CD20 and are, therefore, not depleted by rituximab given as a single course. However, if rituximab is used as a recurrent or maintenance therapy for autoimmune conditions, this may become more of a safety concern as plasma cells are not replenished by memory B cells. While treatment has overall been well tolerated, infusions have been associated with hypersensitivity reactions, Stevens–Johnson syndrome, and type III serum sickness-like illness, and cytokine release syndrome.²⁹ The infusion reactions are more common during the first infusion, and may occur more in lymphoma than in RA. Other notable adverse effects include rare neutropenia and reactivation of hepatitis B infection.

■ AGENTS THAT INHIBIT CELL ADHESION AND/OR MIGRATION ■

Activated T lymphocytes must migrate to sites of inflammation and lymph tissue to exert their diverse effects. The entry of lymphocytes into specific sites occurs through several specific interactions between the adhesion molecules on lymphocytes, including the integrins, and their ligands on endothelial cells. Two ligand pairs that are particularly important for lymphocyte migration and homing are LFA-1 and its counter-receptors intercellular adhesion molecule-1 (ICAM-1) and ICAM-2 and very late antigen-4 (VLA-4) and its counter-receptor vascular cell adhesion molecule-1 (VCAM-1).

NATALIZUMAB

Natalizumab, approved in 2004 for the treatment of multiple sclerosis, is a recombinant humanized IgG₄ mAb directed against the α_4 -subunit of $\alpha_4\beta_1$ integrin; it also binds to and inhibits the function of the $\alpha_4\beta_7$ integrins, whose ligand is mucosal addressin-cell adhesion molecule-1 (MadCAM-1). In addition to blocking the migration of lymphocytes into the central nervous system and intestinal parenchyma, natalizumab induces T-cell apoptosis and anergy and prevents T-cell binding to osteopontin and fibronectin, thereby attenuating T-cell-mediated inflammation.³⁶ In two large clinical trials, natalizumab, either alone or in combination with interferon- β_{1a} , was associated with significantly lower relapse rates, disability, and fewer new multiple sclerosis lesions on MRI. However, only months after FDA approval, natalizumab was withdrawn from the market after three cases of progressive multifocal leukoencephalopathy (PML) were reported.^{36,37} Natalizumab may be brought back to the market with appropriate care and assessment of its long-term safety. The exact role of natalizumab in the development of PML remains unknown but it highlights the importance of pharmacovigilance and potential unforeseen long-term adverse effects related to biological agents.

EFALIZUMAB

Efalizumab, approved in 2003 for the treatment of psoriasis, is a humanized IgG₁ mAb directed against the cell adhesion molecule CD11a. CD11a is a subunit of the LFA-1 molecule on T cells that binds to ICAM-1 on APCs and endothelial cells. In addition to inhibiting activation of T cells, efalizumab also blocks trafficking of lymphocytes into skin by blocking LFA-1/ICAM-1 interaction.³⁸ Efalizumab has been shown to provide greater improvement in skin psoriasis after 3 months of therapy with continued increase in response if therapy was continued for another 3-month cycle. Also, efalizumab therapy significantly improved health-related quality of life and other patient-reported outcomes (e.g., psoriasis symptom assessment and patient global psoriasis assessment) in patients with moderate to severe psoriasis.³⁸ Overall, efalizumab was well tolerated, with most adverse events being mild and occurring most frequently during the first two doses. Due to its ability to modulate adhesion molecules, efalizumab is also being evaluated for the treatment of other autoimmune conditions.

AGENTS THAT INHIBIT IMMUNOGLOBULINS

Immunoglobulins play a significant role in inflammation and have been a target of novel therapeutic agents, especially in the treatment of allergic asthma. For example, immediate hypersensitivity reactions associated with allergic asthma are mediated by complex interaction between IgE, precipitating antigen, and inflammatory cells (e.g., mast cells, basophils). Upon cross-linking of the Fab of IgE to multivalent antigen, IgE activates inflammatory cells through its Fc receptors to release effector mediators (e.g., histamine).

OMALIZUMAB

Omalizumab, approved in 2003 for the treatment of asthma, is a humanized IgG₁ mAb directed against free circulating IgE.³⁹ It binds to IgE in the region of its C3 domain, thereby blocking its interaction with Fcε receptor on mast cells and basophils. This specific binding region is important in two ways: first, it prevents the drug from binding to and cross-linking IgE that is already cell-bound, and therefore does not trigger mast cell activation and degranulation. Second, by not binding the variable region of IgE, it forms complexes with IgE of any specificity. The complex formed is biologically inert and cleared by the reticuloendothelial system without activating complement. Omalizumab has been shown to be effective in reducing the number of asthma exacerbations (by 50%) and decreasing the dose of inhaled corticosteroid.³⁹ Omalizumab was well tolerated with only mild adverse effects such as injection site reaction and respiratory tract infections.

FUTURE DIRECTIONS

The factors that drove the initial introduction of the biologic agents – a clinical need for better outcomes, greater delineation of pathophysiology allowing definition of various targets, and progress in biotechnology allowing development of agents – will no doubt continue to fuel progress in this area. It can be expected that additional mAbs and fusion

receptors, both directed at existing targets as well as against novel targets, will continue to be developed and brought to the clinic. Regarding TNF inhibitors, several molecules are already in late-stage development, including golimumab (a human IgG₁ anti-TNF-α mAb), and certolizumab pegol (a polyethylene glycol-treated humanized anti-TNF-α mAb Fab fragment), and others are in earlier phases of development. Along with the number of agents, it is anticipated that the conditions for which these agents are utilized will also expand. For existing biologic agents, a number of questions remain as to the optimum treatment paradigms and most appropriate patient populations for their use; this will be germane for newer agents as well.

Great progress is being made in developing and fusion receptors that have additional mechanisms of action. Largely in oncology, bispecific mAb, as well as mAb conjugated with various compounds including toxins, chemotherapeutic drugs, or cytokines, are in development.⁴⁰ Such constructs might also find use in nonneoplastic conditions.

As always, the balance between achieving higher levels of efficacy, with disease remission being the ultimate goal, needs to be balanced against safety considerations. For macromolecules, such as mAbs and soluble receptors, there is the potential for optimizing their characteristics, including ease of use, immunogenicity, and cost. For certain targets, it is possible that small-molecule inhibitors may be developed that can address some of these issues. However, as these molecules can be anticipated to have pharmacokinetic, mechanistic, and other important differences from their macromolecular counterparts, this may translate into variable safety and efficacy. Therefore, newer agents of a different class, even those whose putative target is the same as existing therapies, need to be assessed with the same rigor as the currently available agents.

Assessment of proteins of the immune system

Henry A. Homburger, Ravinder Jit Singh

96

Clinical and research laboratories use a variety of analytical methods to detect and measure immunoglobulins and antibodies – the most numerous proteins of the immune system. These methods have been developed over decades and vary considerably in analytical sensitivity and specificity, ease of use, reliability, scope of application in large and small laboratories, and usefulness in clinical medicine and research applications. This chapter provides a broad overview of analytical methods for the detection, qualitative assessment and measurement of immunoglobulins and antibodies. Discussion of this subject is complicated by the fact that methods developed years ago are still in widespread use alongside much newer methods. It is important to provide at least some discussion of older analytical methods in order to understand the basic principles of measurement of immunoglobulins and antibodies. Several of the measurement methods mentioned in this chapter are more appropriate for research applications than for clinical use, and these distinctions are mentioned where they apply.

Measurements of immunoglobulins and antibodies must also be considered from the perspective of their usefulness in different clinical situations. Comprehensive consideration of this subject is beyond the scope of this chapter, but references are made to common clinical applications of measurements of immunoglobulins and antibodies in other chapters devoted to individual immunologic diseases. It is also important to consider immunoglobulins and antibodies from the perspective of their use as reagents in analytical systems of various types, referred to collectively as immunoassays. Reagent antibodies are key ingredients in all the analytical methods discussed in this chapter, irrespective of whether the analyte being measured is an immunoglobulin molecule, a specific antibody, or an unrelated molecule such as a microbial antigen or endogenous antigen.

The chapter is divided into sections devoted to consideration of the qualitative and quantitative assessment of immunoglobulin proteins, the measurement of antibodies by qualitative, semi-quantitative and quantitative methods, advanced analytical methods for the identification and qualitative analysis of proteins and antibodies (proteomic techniques), and proficiency testing programs designed to determine the performance of laboratories that perform clinical tests for immunoglobulins and antibodies. Throughout the chapter, the discussion of older analytical

methods is approached from the perspective of principles of immunochemistry illustrated by these methods. In some instances several different analytical methods are in widespread use for the same clinical applications, e.g., detection of monoclonal immunoglobulin paraproteins (M-proteins) or measurement of autoantibodies, and the advantages and limitations of each method are mentioned.

It is important at the outset to recognize an essential difference between immunoglobulins and antibodies as analytes in immunoassays. When measuring an immunoglobulin, the analytical method relies upon the fact that all molecules of immunoglobulin protein that react in the assay possess a common chemical structure, i.e., an epitope defined by several amino acids associated with the constant region of the immunoglobulin heavy or light chain.¹ Immunoglobulin molecules that possess the epitope all react in the immunoassay regardless of differences in the molecular structure or amino acid sequence of other domains of the heavy or light chains. By contrast, immunoassays that measure antibodies rely on the fact that all the antibodies of interest react with an antigen of defined structure. The antibodies that are detected often vary extensively in the strength with which they bind to the target antigen, a property referred to by the terms affinity and avidity, and thus are not chemically identical even in the portion of the molecules that react with antigen.² For this reason, it is more difficult to measure antibodies quantitatively, and it is often difficult to compare the results of antibody measurements performed by different analytical methods. Examples of this phenomenon are presented in the sections devoted to the measurement of antibodies.

■ IMMUNOGLOBULINS: QUALITATIVE ASSESSMENT AND CHARACTERIZATION ■

The common structural elements of immunoglobulins are the heavy and light polypeptide chains. There are five different polypeptide heavy chains, γ , α , μ , δ and ϵ , and two different polypeptide light chains, κ and λ . Each heavy chain and light chain is composed of several domains that contain common structural elements (constant regions) and a variable

Table 96.1 Immunoglobulin levels (age-related reference ranges in mg/mL)

	IgG	IgM	IgA
Cord blood	6.36–16.06	0.06–0.25	0.01–0.03

9–10 years	6.08–15.72	0.52–2.42	0.45–2.36
Adult	6.39–13.49	0.56–3.52	0.70–3.12

(antigen-binding) domain (Chapter 4).³ Each set of heavy chains is associated with a set of light chains according to the following molecular formulae for monomeric forms of intact immunoglobulin molecules: γ_2 , κ_2 or γ_2 , λ_2 (IgG); μ_2 , κ_2 or μ_2 , λ_2 (IgM) and so forth. IgG, IgD and IgE molecules are always found as monomeric units composed of two heavy and two light chains, whereas IgA and IgM are present in multimeric forms.³ IgG is present in normal adult sera in concentrations of 8–16 mg/mL. Molecules of IgG can be further separated into four unique subclasses based on differences in molecular structure of the γ heavy chain. The four subclasses are distributed in serum in the following proportions: IgG₁ 66%, IgG₂ 23%, IgG₃ 7%, and IgG₄ 4%. IgA is present in serum at concentrations of 1.4–4.0 mg/mL and is the principal immunoglobulin in secretory fluids. In secretions, IgA exists as a dimer that also contains a protein J chain and another peptide chain called secretory component (SC). The latter is synthesized by mucosal epithelial cells and is joined to dimeric IgA during its movement through epithelial cells from the interstitial fluid to the luminal surface. Most IgM molecules are composed of five monomeric subunits linked by disulfide bonds and a J chain to constitute a pentameric structure. The serum concentration of IgM ranges from approximately 0.5 to 2.0 mg/mL. IgD is a minor immunoglobulin component in serum at approximately 0.4 mg/mL. IgE is present in the lowest concentration in serum, typically 17–450 ng/mL in nonatopic adults. IgE is the principal skin-sensitizing immunoglobulin associated with immediate hypersensitivity reactions in humans (Chapter 100).

Immunoglobulin levels vary with age, increasing during childhood (Table 96.1). They also vary by gender and race, although these differences are generally not clinically significant. The amino acid sequences of the heavy chain constant regions define the immunoglobulin classes or isotypes and provide a common structure for the molecule, whereas the variable regions are associated with antibody diversity. The constant region also determines the biological activities of different immunoglob-

ulin classes and subclasses. The constant regions of immunoglobulin isotypes and subclasses contain epitopes that enable the preparation of reagent antibodies needed to perform immunoglobulin measurements in general clinical use. The changes often observed clinically in serum immunoglobulin levels include increased or decreased concentrations of one or more classes of immunoglobulin protein, and excessive production of a monoclonal immunoglobulin (M-protein) or free light chain in plasma cell dyscrasias and certain lymphoproliferative diseases (Chapter 78).

The following qualitative and semi-quantitative methods have two primary uses: to detect the presence of monoclonal M-proteins and to rapidly estimate the quantity of immunoglobulins. They provide only approximate measures of the quantities of individual immunoglobulins. The analysis of body fluids other than serum may require the use of concentrated samples, e.g., 50–100-fold for urine or cerebrospinal fluid.

ELECTROPHORETIC METHODS

The migration of immunoglobulins on agarose electrophoresis is evidence of their diversity.^{4,5} In the serum protein electrophoresis depicted in Figure 96.1, the stained protein bands representing albumin, α_1 -, α_2 - and β -globulins are easily demonstrated. Note that several of the more abundant protein bands, such as albumin, are sharply delineated, whereas the area representing the immunoglobulins (the γ region) is broad and diffuse. The lack of resolution in the γ region is due to the presence of many electrophoretically heterogeneous immunoglobulins that migrate in the same region of the electrophoregram. Small differences in the amino acid composition of immunoglobulins from healthy individuals account for the expected polyclonal display of γ -globulins. Examples of subjects with polyclonal hypergammaglobulinemia, an M-protein and hypogammaglobulinemia are depicted in Figure 96.2.

ZONE ELECTROPHORESIS

Most proteins display a net charge in an electrical field, and can be separated electrophoretically. Serum proteins are amphoteric and their net charges are dependent on the pH of the buffer solution. A protein in buffer with a pH below the isoelectric point migrates toward the anode; conversely, in buffer with a pH above the isoelectric point, a protein will migrate toward the cathode. The size and shape of a protein molecule, the ionic strength of the buffer, the frictional resistance of the supporting medium, the temperature of the reaction and the intensity and duration of the applied current all influence the migration of proteins in a typical electrophoresis.^{6,7} Clinical laboratories most commonly use barbital buffers at pH 8.6 to perform the serum protein electrophoresis (SPEP) test. Under these conditions immunoglobulins have little net charge and tend to be influenced by endosmosis. In the past, paper and cellulose acetate were commonly used as supporting media. The new standard is agarose, which offers less frictional resistance and clearer delineation of more discrete protein bands⁶ (Fig. 96.1).

In a typical SPEP analysis, the samples to be tested are applied to a buffer-saturated support medium such as agarose and placed on an electrophoretic apparatus that consists of buffer reservoirs and positive and negative electrodes. The application of electric current to the supporting medium separates the proteins according to their net charge at a standard pH 8.6. All major proteins except some immunoglobulin

Fig. 96.1 Plasma protein electrophoresis pattern on agarose gel. Some of the major proteins in each region are shown here in an artist's rendition for clarity.

Fig. 96.2 High-resolution protein electrophoresis of serum from 10 different subjects. Lane 7 demonstrates an M-Protein; lane 4 demonstrates polyclonal hypergammaglobulinemia; lane 5 indicates probable hypogammaglobulinemia.

components migrate toward the anode. Following electrophoresis for a standardized time or by observation of a marker dye, the proteins are stained with amido black or Coomassie blue. The strips containing the stained proteins are then visually reviewed and separated proteins are measured semi-quantitatively with a densitometer.⁶

Five zones are readily identified with a cellulose acetate protein electrophoresis: albumin, α₁-globulin, consisting primarily of α₁-antitrypsin; α₂-globulin containing haptoglobin and α₂-macroglobulin; β-globulin, comprising transferrin and complement components; and the γ globulins. As many as 12 discrete regions can be visualized with higher-resolution protein electrophoresis using agarose and controlled voltage and temperatures. These are shown in Figure 96.2, along with the serum proteins in each region.

Other body fluids are commonly studied in the clinical laboratory by electrophoresis. Urine samples are routinely tested in patients with serum M-proteins to identify the M-protein components, particularly light chains; and cerebrospinal fluid can be tested for oligoclonal immunoglobulins suggestive of certain disorders, such as multiple sclerosis. The conditions under which these fluids are analyzed may differ from those used for serum, and attention should be paid to the manufacturers' instructions.

Serum protein electrophoresis is most commonly ordered to investigate sera for the presence of monoclonal and/or polyclonal immunoglobulins.⁸ Hypogammaglobulinemia may be detected as well, but SPEP is not particularly sensitive and is not the preferred method unless other methods are not readily available. A monoclonal M-protein should be

KEY CONCEPTS

QUALITATIVE AND SEMI-QUANTITATIVE IMMUNOGLOBULIN TESTING

Protein electrophoresis:

- >> Useful to evaluate body fluids for the presence of monoclonal immunoglobulins (M-proteins).
- >> Useful to estimate changes in the concentrations of M-proteins.

Immunofixation electrophoresis, capillary zone electrophoresis with immunosubtraction, and immunoelectrophoresis:

- >> Useful to characterize the heavy and light chains of M-proteins.
- >> Capable of identifying small M-proteins present in low concentrations that may not be apparent on protein electrophoresis.

further evaluated by other methods and hypogammaglobulinemia should be confirmed by quantifying the levels of IgG, IgM and IgA. Densitometric analysis of stained proteins after SPEP is an acceptable method for following the response to therapy of diseases characterized by M-proteins once the specific diagnosis has been established.

IMMUNOFIXATION ELECTROPHORESIS

Immunofixation electrophoresis (IFE) has largely replaced immunoelectrophoresis (IEP) (see below) for establishing the presence and isotype of a monoclonal immunoglobulin M-protein^{8,9} (Fig. 96.3). IFE is easier to perform, is somewhat more sensitive, and is easier to interpret than IEP. IFE combines the resolution of zone electrophoresis and the specificity of an antigen–antibody precipitin reaction. The initial step in the IFE procedure involves creating replicate lanes of high-resolution protein electrophoresis. After the proteins are separated, but before staining, the replicate electrophoretic strips are each incubated with a different specific antiserum, either in solution or with an antiserum-soaked membrane. Laboratories usually include antisera to the heavy chains of IgG, IgA and IgM, and κ and λ light chains, but leave one lane blank to observe the appearance of an untreated (standard) SPEP. The quality of antisera used to stain the separated immunoglobulins is critical in that they must be specific for the intended targets and of high titer. The protein band and its antiserum form a precipitate on the gel at the region of antibody–antigen equivalence (see below), which is then washed to remove unreacted proteins. Following staining with amido black or Coomassie blue, the gel is reviewed manually. The location of the immunoprecipitate depends on the electrophoretic mobility of the specific M-protein.

Most laboratories use IFE after screening samples with the SPEP test and/or quantitative immunoglobulin measurements.⁹ Although serum is the most common sample source, urine or cerebrospinal fluid can also be examined to detect and/or characterize M-proteins or their fragments. IFE has several advantages over IEP, including rapid turnaround time (2 hours, versus overnight incubation); increased sensitivity; better resolution; and ease of interpretation compared to IEPs. IFE is particularly useful for characterizing small M-proteins and nonIgG M-proteins.

Fig. 96.3 Immunofixation of serum from a patient with an IgA- λ M-protein. Lane 1 shows a serum protein electrophoresis. Lanes 2–6 represent serum samples from the same patient reacted with monospecific antisera to IgG, IgA, IgM, κ and λ .

CLINICAL PEARLS

ASSESSMENT OF IMMUNOGLOBULINS

- >> Initial assessment is performed by protein electrophoresis and by quantification of immunoglobulins and free light chains by nephelometry.
- >> Useful in the diagnosis of a monoclonal immunoglobulin (M-protein, multiple myeloma or Waldenström's macroglobulinemia).
- >> Useful to estimate the quantity of M-protein or response to therapy:
Electrophoresis is often more useful than nephelometry for following the level of a monoclonal M-protein.
- >> Second order testing is performed by immunofixation analysis or immunoglobulin analysis by capillary zone electrophoresis with immunosubtraction to identify and characterize the heavy and light chains of monoclonal M-proteins.

The disadvantages of IFE include the increased quality, quantity and cost of antisera required. Optimal resolution requires that the amounts of antisera be determined for each patient sample to avoid either excess dilution or excess antibody. In addition, because of the increased sensitivity of IFE, smaller bands are more frequently identified. These may be of uncertain clinical significance, leading to some difficulties in interpretation.

CAPILLARY ZONE ELECTROPHORESIS (CZE)

This is a more recent electrophoretic technique that provides increased sensitivity, speed, and the potential for automation.¹⁰ Commercial instruments aimed at detecting M-proteins are available and are an attractive alternative to IFE for those laboratories that process large numbers of samples.

In a typical CZE analysis, samples are aspirated into narrow-bore, negatively charged capillary tubes. An electrical current is applied and proteins migrate toward the cathode. The fractions are optically quantified at a wave length of 215 nm to produce a virtual electrophoregram similar to those seen with traditional SPEP. There is no staining of the proteins and up to 40 samples per hour can be processed. CZE has been used to characterize M-proteins by a process called immunosubtraction.^{10, 11} The patient's specimen is absorbed with beads to which individual specific antisera, including anti- μ , anti- γ , anti- α , anti- κ , and anti- λ , are bound. An M-protein present before immunosubtraction is diminished or absent following incubation with appropriate class-specific antiserum. Recent comparisons of CZE and agarose electrophoresis with IFE indicate similar analytical sensitivity for detecting and characterizing M-proteins.¹¹ CZE and immunosubtraction are relatively new techniques. Larger laboratories will be drawn to the possibility of automation, speed, and potential cost savings. Clinicians will be drawn to the speed and potential improvement in sensitivity of this technology compared to older analytical methods.

IMMUNOELECTROPHORESIS

Immunoelectrophoresis (IEP) is an older method for qualitative analysis of M-proteins in serum and urine. IEP is a two-step procedure that combines the principles of zone electrophoresis and immunodiffusion. The method is mentioned here as it is still used by some clinical laboratories. In a typical IEP analysis, serum proteins are first separated by electrophoresis in a supporting medium such as agarose bound to a glass slide or plastic sheet. The separated proteins are reacted for up to 72 hours with specific antisera placed in troughs parallel to the electrophoretic migration. Antigen and antibody diffuse toward each other, forming elliptical precipitin arcs. The shape, position, and size of each arc demonstrate the specific characteristics of each protein. γ -Globulin from a healthy individual will form a balanced, evenly distributed smooth arc when reacted with antisera specific for the more prevalent heavy chains or light chains. Excess monoclonal production of any one isotype of immunoglobulin leads to distortion by thickening or bowing of the uniformity of the precipitation arc. In this way, M-proteins are visualized qualitatively. The quality and quantity of antisera used are not as critical as in IFE.

IEP has been largely supplanted for evaluating immunoglobulins in serum and other body fluids. Nevertheless, many small laboratories throughout the world still use IEP to detect and/or characterize M-proteins in the serum or urine. IEP is slower, less sensitive, and more difficult to interpret than IFE. IEP fails to detect some small monoclonal M-proteins because the most rapidly migrating immunoglobulins present in the highest concentrations may obscure the presence of small M-proteins.

■ QUANTITATIVE METHODS FOR MEASURING IMMUNOGLOBULINS: PRECIPITIN METHODS ■

The levels of immunoglobulins in a healthy population vary markedly with age, and to a lesser extent with gender, racial background, environmental factors and genetic makeup.¹² Each laboratory must verify

the reference values for immunoglobulins by age, often by assessing a group of healthy individuals and comparing those results with data in the literature and/or data supplied by the reagent manufacturer. Although there are international standards for immunoglobulin measurements, variations in methods and techniques have been associated with differences between laboratories in reference ranges for immunoglobulins.¹²

Immunoglobulin levels outside the reference range include low levels seen in hypogammaglobulinemia and increased levels associated with polyclonal hypergammaglobulinemia. Polyclonal hypergammaglobulinemia is often associated with chronic inflammatory diseases, including infectious diseases, autoimmune diseases and chronic liver diseases. Monoclonal hypergammaglobulinemia is a hallmark of multiple myeloma and Waldenström's macroglobulinemia. Immunoglobulins are commonly quantified to evaluate suspected deficiency, to monitor immunoglobulin replacement therapy, and to monitor levels in patients with monoclonal immunoglobulins. Adequate monitoring of a monoclonal M-protein often requires the use of other qualitative techniques, as described above.⁹

RADIAL IMMUNODIFFUSION (RID)

RID is an older method based on the classic precipitin reaction in which antigen and antibodies react to form precipitates in liquid or semi-fluid media.¹³ Under conditions of antibody excess, the quantity of the precipitate is directly related to the quantity of antigen in the test sample. Ouchterlony²⁶ demonstrated that precipitins form in agar or agarose media in a manner related to the relative quantities of each. In a typical RID analysis, the amount of precipitin, as measured in distance migrated from the antigen well, is mathematically related to the concentration of antigen added to the well.

RID uses a predetermined dilution of specific antiserum mixed with agar or agarose in a Petri dish or on a glass slide. A series of small wells are cut in the agar and filled with samples containing antigen. As the antigen diffuses into the agar it forms a precipitate with the antibodies contained in the gel. Once antigen-antibody equivalence is reached, an opaque precipitin ring develops around the antigen well. The diameter of the precipitin ring is proportional to the concentration of antigen in the test solution or standard added to the center well. The diameter may be measured either at the endpoint, when the antigen has completely reacted with antibody (typically 48–72 hours), or after a fixed diffusion time, usually 24 hours. The concentration of the unknown sample is estimated by measuring the diameter of the ring produced by the sample and plotting this on a concentration-diameter curve, established using standards containing known amounts of the antigen. The lower limit of sensitivity of RID is approximately 0.5 mg/L. Within limitations, the ring diameter for a given antigen concentration can be increased by reducing the antiserum concentration in the gel.

RID is used in many smaller laboratories to measure the concentrations of common proteins, including serum immunoglobulins and IgG subclasses. The method is simple to perform and requires very little equipment. The major limitations include the amount of time required, the relative imprecision of the assay, with coefficients of variation often greater than 10%, relative insensitivity, and dependence on antigen quantity and configuration. In rare situations RID can lead to large errors in estimates of immunoglobulin concentrations, including

KEY CONCEPTS

QUANTITATIVE IMMUNOGLOBULIN TESTING

Nephelometry:

- >> Most commonly used method for measuring immunoglobulin levels.
- >> Can be used to measure immunoglobulins, immunoglobulin subclasses and free light chains.
- >> Less variable and more sensitive than radial immunodiffusion.

Radial immunodiffusion:

- >> Used by some small laboratories to quantify immunoglobulins and other serum proteins.
- >> More variable and slower to perform than nephelometry.

estimations of IgM levels in patients with 7S IgM M-proteins, patients with high levels of rheumatoid factor, and some patients with IgA deficiency who may have antibodies that react with antisera used to prepare the RID plate.

ELECTROIMMUNODIFFUSION (EID)

Electroimmunodiffusion is a modification of RID used in occasional cases and in some research settings to measure specific proteins.¹⁴ The technique differs from radial immunodiffusion in its use of an electric field to induce migration of the protein antigen into an antibody-containing gel. Antigen–antibody complexes form a visible precipitate in the form of a cone or ‘rocket.’ The height of the cone is proportional to the amount of antigen in the sample. A standard curve is constructed and the concentration of the protein unknown is extrapolated from the curve. The sensitivity of the EID method is of the order of 0.01–0.05 mg/L.

NEPHELOMETRY

Nephelometry has largely replaced RID in most clinical laboratories as the preferred method for measuring intact immunoglobulins, immunoglobulin light chains and many other proteins in body fluids.^{12, 15} Nephelometry is a modification of the basic precipitin reaction that relies on light-scattering by soluble immune complexes in solution (Figs 96.4 and 96.5). The amount of scatter produced by soluble immune complexes is measured in a photoelectric cell as optical density. As the concentration of antigen increases, scattered light increases. In contrast to the standard precipitin reaction, which requires that the concentrations of antigen and antibody be at equivalence, nephelometry often performs best with excess antibody.

In a typical nephelometric assay for immunoglobulin, a standard curve is developed by reacting increasing concentrations of the antigen of interest with a constant, large quantity of specific antiserum. Increasing amounts of immune complexes scatter more light, and the intensity of scattered light is directly related to the concentration of antigen. Antigen can be measured accurately in the antibody excess portion of the precipitin curve, and to maintain this relationship, increased antigen concentration requires additional dilutions of the sample.

Fig. 96.4 Precipitin reaction. Antigen molecules are represented as having three different antigenic sites (epitopes) on their surface. Three different types of antibodies are illustrated, each having binding regions for one of the three types of antigenic sites. (A) Near the equivalence point, lattice formation occurs and a precipitate forms. (B) In the presence of excess antigen the concentration of antibody is insufficient for cross-linking. Lattice formation does not occur and complexes are soluble. (C) In the presence of excess antibody, lattice formation does not occur and complexes are soluble. (D) In the presence of a monoclonal antibody each antigen molecule is bound at a single site. No cross-linking can occur and complexes remain soluble.

Endpoint (or fixed-time) nephelometry measures the maximum scattered light after an antigen–antibody reaction has reached equilibrium, or after a fixed reaction time. The antigen concentration in the unknown sample is calculated from a response curve produced with reference standards containing known amounts of the antigen tested under identical conditions.

Rate or kinetic nephelometry is an alternative method in which the peak rate of immune complex formation is measured.^{15, 16} As soluble immune complexes are formed during an antigen–antibody reaction, the quantity of light scattered over time can be plotted as a sigmoid curve. The upper inflection point in the curve represents the peak rate of immune complex formation and is directly proportional to the antigen concentration. The antigen concentration of an unknown sample is calculated by comparing the sample's peak rate of light scatter to an established reference curve. Rate nephelometry has been automated by

Fig. 96.5 Nephelometry. Light scatter by soluble immune complexes is measured at an acute angle to the incident light source.

several commercial manufacturers. Available instruments provide an automated platform of reagents, with barcoding of test specimens and rapid analysis with high throughput. The coefficients of variation for measurements of intact immunoglobulins and free immunoglobulin light chains are typically in the range of 5%.

According to recent inter-laboratory proficiency surveys from the College of American Pathologists, the vast majority of clinical laboratories use nephelometric methods to measure immunoglobulins.¹⁷ Fewer than 2% use RID. Some disadvantages of nephelometry include increased costs for instruments and reagents, although these are compensated for by savings in personnel costs. Other potential problems include reagent antisera, i.e., poor reactivity of certain commercial antisera with unusual M-proteins; poor linearity of measurement of some M-proteins leading to inaccurate quantification; and temperature maintenance problems with the measurement of cryoglobulins. In general, from a clinical perspective it is preferable to monitor the quantity of an M-protein during therapy of a plasma cell proliferative disease by electrophoresis with densitometric quantification.⁹ Nephelometric methods can also be subject to interferences caused by particles or pigments in serum that increase background light scatter and make interpretation difficult or impossible.

IMMUNOMETRIC METHODS

The first widely adopted immunometric assays were competitive displacement radioimmunoassays used to measure hormones in human plasma.¹⁸ More recently, radiolabeled antigens have been largely supplanted by enzyme or chemiluminescent labels in most displacement

KEY CONCEPTS

IMMUNOASSAYS

Precipitin assays:

- >> Useful for measuring both immunoglobulins and antibodies.
- >> Except for nephelometry and certain agglutination methods, less sensitive than immunometric assays and immunofluorescent microscopy.
- >> Tend to be used in smaller laboratories and for infrequent analyses.

Immunometric assays:

- >> Useful for measuring immunoglobulins and antibodies.
- >> Measurements based on competitive displacement or two-site (sandwich) techniques.
- >> Antigen or antibody is labelled with an enzyme, fluorophore or chemiluminescent molecule.
- >> Sensitive to nanogram or picogram quantities of analyte.

assays.^{19,20} In a typical competitive displacement assay, labeled and unlabeled antigen are incubated with limited quantities of first-stage antibody. The two species of antigen compete for binding to the first-stage antibody. A standard curve is developed by adding standards that contain increasing quantities of unlabeled antigen. The degree of inhibition of the trace amount of labeled antigen by unlabeled antigen provides an indirect measure of the concentration of the unlabeled species. After incubation, the antigen-antibody complexes are separated from unbound labeled and unlabeled antigen, and 'bound' or 'free' labeled antigen is measured to construct a standard curve.

Noncompetitive immunometric assays are now more popular than displacement assays.²⁰ In a noncompetitive (sandwich) assay, specific antibody bound to a solid phase, e.g., a polystyrene particle or microtiter plate, is used to 'capture' the antigen of interest. An aliquot of test specimen is incubated with antibody bound to the solid phase, allowing the antigen to react with the first-stage antibody. The excess specimen is washed away and a second labeled antibody, also reactive with the antigen, is added. Excess second-stage labeled antibody is washed away after a second incubation, and the binding of standards and unknowns is measured. Unknowns are compared to a standard curve generated with calibrator materials having known concentrations of antigen. Noncompetitive immunometric methods are approximately as sensitive as displacement methods. Sensitivity is determined by the affinities of reagent antibodies, and by the amplified signal obtained from the chemical label.²¹

In general, immunometric assays of either type have excellent sensitivity, reasonable precision with coefficients of variation in the range of 10% for measurements of proteins, and may be used to measure antigens of all types in human body fluids. Immunoglobulins present in serum in very low concentrations, especially IgE, are effectively measured by these techniques.

Enzyme-linked immunosorbent assay (ELISA) is the most popular technical version of immunometric assay in current use. There are many variations of the basic ELISA method, including both competitive and

KEY CONCEPTS

SPECIFIC ANTIBODY TESTING

- >> Can be performed by a variety of methods, including precipitin-based immunoassays, fluorescence microscopy, and immunometric assays (ELISA).
- >> Most measurements are semi-quantitative and quite variable.
- >> Tests performed with crude antigens are often used for screening.

noncompetitive assays. As noted above, ELISA is a sensitive method capable of measuring proteins in nanogram or picogram quantities, without the use of radionuclides. ELISA assays are so named because reagent enzymes are used to label either the antigen standard or the second-stage antibody in competitive displacement and noncompetitive (sandwich) assays, respectively (see below).

DETECTION AND MEASUREMENT OF SPECIFIC ANTIBODIES

Laboratory testing for specific antibodies and autoantibodies is useful clinically to screen for disease, to establish specific diagnoses, and to monitor the clinical courses of certain diseases. This is particularly true for diseases in which the antibody response is involved in the pathogenesis, e.g., immediate hypersensitivity diseases, or where antibodies serve empirically as disease-specific markers or independent prognostic indicators.

Antibodies are routinely detected and measured by a variety of immunoassay methods. In virtually all cases, the methods rely on the use of antigens as analytical reagents. Reagent antigens can be complex mixtures of molecules, e.g., an allergen mixture in a test for IgE antibodies or highly purified 'native' or recombinant molecules, e.g., small nuclear ribonucleoproteins in a test for IgG antibodies to extractable nuclear antigens. Many reagent antigens of clinical interest are large molecules with several antigenic sites (epitopes) that react with antibodies of clinical interest in patients' specimens.^{22, 23}

Clinical applications of tests for specific antibodies are directly related to the nature of the reagent antigens. For example, tests that employ crude or complex antigen preparations, such as the tissue substrates used in the test for antinuclear antibodies, are useful primarily as screening tests, whereas tests that employ highly purified or recombinant antigens, such as tests for antibodies to some microbial antigens or extractable nuclear antigens, detect antibodies that are disease-specific markers.²⁴

Tests performed with purified or recombinant antigens are often used to detect disease-specific antibodies. The nature of the reagent antigen also influences the precision and accuracy of antibody measurements. Measurements performed using a crude antigen as reagent tend to be semi-quantitative and imprecise, with the result often expressed as a titer (i.e., the reciprocal of the dilution of test specimen used in the assay). In contrast, a highly purified antigen may be used to prepare a pure preparation of specific antibodies by affinity chromatography,

which enables calibration of the assay system either in mass units (e.g., micrograms of antibody protein per liter) or in arbitrary quantitative units.

The antigens of interest in clinical immunology belong to several different chemical classes, including proteins and glycoproteins, lipids, nucleic acids, carbohydrates and haptens. Many of the analytic methods discussed below are adaptable for use with each of these classes of antigen. Exceptions are noted where they apply.

PRECIPITATION METHODS

Analytical methods that rely on the principles of immunoprecipitation are among the oldest methods in clinical immunology. They are applicable to the detection of both specific antibodies and immunoglobulin proteins (as discussed above). Precipitation methods are based on the antigen-antibody precipitin reaction originally described by Heidelberger and Kendall.²⁵ In this reaction, a multivalent antigen reacts with antibodies in a fluid or semi-solid matrix such as agar gel to form an insoluble lattice of antigen-antibody complexes. The presence of a precipitin indicates the presence of specific antibodies to one or more of the antigens in the antigen reagent. Precipitation occurs over a range of concentrations of antigens and antibodies referred to as the zone of equivalence (Fig. 96.4). If the concentration of either reactant is too great, precipitation does not occur and only soluble complexes are formed.

A modification of the basic immunoprecipitation technique, called double immunodiffusion, is commonly used in both research and clinical laboratories to detect specific antibodies.^{26, 27} In this adaptation of the precipitin method, an aqueous solution of reagent antigen is placed in the center well of an agar slide and positive control sera and specimens to be tested for the presence of specific antibodies are pipetted into surrounding wells. After 24–48 hours of incubation, which permits diffusion of antigens and antibodies throughout the gel, precipitin lines form that can be detected visually. The specificity of antibodies in the test specimen is evaluated by examining the pattern of convergence between the unknown precipitins and a control that contains antibodies of known specificities. The possible reactions include identity (fusion), partial identity (one spur) and nonidentity (two spurs), (Fig. 96.6).

The double immunodiffusion method is simple to perform and requires no special equipment. However, the technique is qualitative and is sensitive only to concentrations of antibodies greater than approximately 0.1 µg/mL. The relative lack of sensitivity of this method limits its application in the clinical laboratory to situations in which patients' sera contain relatively high concentrations of specific antibodies. The results of double immunodiffusion tests are also subject to errors of interpretation. False negative results may occur if the concentration of antigen is not carefully adjusted to produce a zone of equivalence with the concentration of antibodies usually encountered in patients' specimens. In addition, multiple precipitin lines of unknown specificity can be seen with clinical specimens, and these precipitins can obscure identification of specific antibodies of clinical interest. The double immunodiffusion method cannot be used to detect antibodies to haptens and monovalent antigens, which fail to form an insoluble lattice. Despite these limitations, the method is still in widespread use in clinical laboratories for the detection of autoantibodies, including antibodies to small nuclear ribonucleoproteins (SSA/Ro, SSB/La, Sm, and SmRNP) and enzymes (topoisomerase 1 and RNA synthetases) in patients with systemic rheumatic diseases.

Fig. 96.6 Double immunodiffusion for autoantibodies to extractable nuclear antigens U₁RNP and Sm. The center well was loaded with U₁RNP/Sm antigen. Outside wells were loaded with control sera or patients' sera as follows (counterclockwise from top well): anti-U₁RNP and anti-Sm control, patient 1 in duplicate; anti-U₁RNP control, patient 2 in duplicate. Precipitin formed with serum from patient 1 shows line of identity (fusion of precipitins) with anti-U₁RNP control sera.

Counterimmunoelectrophoresis (CIEP) is another modification of the basic immunoprecipitation technique that utilizes electrophoresis to enhance the rate of migration of antigen and antibodies in a gel matrix. By adjusting the pH of the electrophoresis buffer, antigens and specific antibodies are made to migrate in opposite directions toward the center of the slide, where immunoprecipitation can occur. CIEP is a somewhat more sensitive technique than conventional double immunodiffusion, but it is technically demanding and has limited application in the clinical laboratory for detecting most specific antibodies.²⁸

AGGLUTINATION METHODS

Agglutination is the aggregation or clumping of visible, discrete particles in an antigen–antibody reaction to form a larger mass.^{13, 29} The fundamental immunologic principle of agglutination reactions is the same as previously described for precipitin reactions. Initially, antigen–antibody recognition occurs, followed by binding, and visible aggregation of antigen particles. Occasionally agglutination is incomplete because the necessary antibody bridging of adjacent antigen particles fails to occur.

Agglutination assays for specific antibodies can be performed using insoluble native antigens such as bacterial cells, antigen-coated particles such as latex beads, or red blood cells to which antigens have been attached by chemical coupling. Agglutination assays require a stable

particle on which antigen is accessible for binding, and a reaction solution of proper ionic strength and viscosity to prevent incomplete agglutination. Most commercially available agglutination tests that are designed to detect antibodies specify the use of serum (not plasma) or cerebrospinal fluid. The sensitivity and specificity of these tests are determined by the purity of the antigens coupled to the insoluble indicator particles.

In general, the advantages of agglutination methods are their ease of performance; speed of performance, usually requiring less than 10 minutes; their high degree of analytic sensitivity (often comparable to immunometric methods); and the enormous variety of antibodies that can be detected. In addition, with the exception of cold agglutinins (typically IgM antibodies), the tests are usually not affected by temperature. One of the major disadvantages of agglutination methods is that the reactions are at best semi-quantitative. For example, although qualitative test results are highly reproducible, for most test systems the results are only accurate to a fourfold difference in antibody titer. The other important disadvantage of agglutination methods is their susceptibility to false negative reactions caused by the prozone phenomenon. Prozone refers to the absence of agglutination in conditions of extreme antibody excess, which results in poor lattice formation.

Agglutination techniques are routinely used in the diagnosis of infectious diseases, in transfusion medicine for typing of blood cells, and in commercial assays for the detection of autoantibodies in patients with autoimmune diseases. Numerous agglutination-based diagnostic tests are available because of the ease with which test reagents can be developed. For example, some red blood cells, bacteria, and fungi can be agglutinated directly by serum antibodies. Indirect agglutination tests are also available in which a vast repertoire of soluble antigens can be passively adsorbed or chemically coupled to red blood cells or inert particles.

Direct agglutination

Direct agglutination is the aggregation of particles brought about by the interaction of specific antibodies with particulate antigens. To agglutinate an antigen, all that is required is a reaction solution of the proper ionic strength and an antibody with two or more receptors that cross-link adjacent antigen particles (Fig. 96.7). IgM antibodies are more efficient than IgG antibodies in agglutination reactions. IgM antibodies usually aggregate particulate antigens based on the size of the antibody molecule, whereas IgG antibodies may require the addition of substances such as bovine serum albumin or dextran to alter the viscosity and charge of the reaction solution before agglutination can occur.²⁹ In some direct agglutination tests, red blood cells or bacteria are treated with enzymes such as papain or DNase to increase the exposure of surface antigens, remove allosteric interferences, or alter the configuration of external membrane components to enhance the agglutination reaction. For direct agglutination tests, if the techniques are highly standardized the only reagents necessary for a functional assay are positive and negative controls for qualitative tests, a serum that can be diluted for quantitative tests, some measurement of antigen concentration (such as a McFarland standard for opacity), and a control for nonspecific agglutination.

The most common clinical use of the direct agglutination test procedure is in transfusion medicine, i.e., ABO typing of erythrocytes.³⁰ Direct agglutination tests are also widely used for serotyping of bacteria, e.g., *Campylobacter* and other enteric pathogens involved in outbreaks of

Fig. 96.7 Direct agglutination reaction. Particulate antigen reacts with specific antibodies to form an insoluble matte. Chromagen particles are trapped in the matte, indicating that the reaction has taken place.

foodborne human gastroenteritis, and in the diagnosis of certain infectious diseases.^{31, 32}

Indirect agglutination

The most widely used agglutination methods are so-called indirect assays in which antigen is attached to a carrier particle, either covalently or by adsorption. The two most common indirect agglutination methods use red blood cells and polystyrene beads as carriers. A number of bacterial antigens, viruses and microbial toxins adsorb directly to red blood cells, but for many applications of the indirect hemagglutination method it is necessary to treat the carrier cells with coupling reagents such as tannic acid, bisdiazobenzidine or glutaraldehyde to couple the antigen to the carrier cells.²⁹ Covalent coupling of antigens to polystyrene beads is often performed using carbodiimides or other chemical coupling reactions. Indirect agglutination assays that use polystyrene carrier beads are used to detect antibodies to bacteria, fungi, rickettsial and parasitic antigens, as well as certain viruses, including rubella, HIV, rotaviruses and Epstein-Barr virus. Indirect agglutination assays are also available to detect autoantibodies, including antibodies to various nuclear antigens and dsDNA.

A third form of agglutination test is the antibody-mediated incomplete agglutination reaction. The direct antiglobulin test used in the diagnosis of autoimmune and drug-induced immune hemolytic anemia and to determine antibody to Rh antigens on erythrocytes is an example. In this technique, antiglobulin antibodies produced in a heterologous species are added to detect subagglutinating or nonagglutinating

amounts of anti-erythrocyte antibodies. The direct antiglobulin test detects specific antibodies or other serum proteins that bind to a patient's erythrocytes. The indirect antiglobulin test is a two-stage reaction in which the patient's serum is first incubated with commercially available red blood cells, after which an antiglobulin antiserum is added. Still another variation of the indirect antiglobulin test uses enzyme-treated erythrocytes to increase assay sensitivity.

Finally, flocculation, a term used mainly in syphilis serology, describes the reaction of a microscopically visible particulate antigen with an invisible substance (antibody) to form aggregates that either can be seen microscopically, as in the Venereal Disease Research Laboratory (VDRL) slide test, or visualized by the addition of an inert particle such as charcoal, which becomes entrapped in the antigen-antibody lattice, as in the rapid plasma reagin (RPR) card test for syphilis. In these tests the antigen-antibody reaction particles stay suspended rather than settling in a clump or forming a matte pattern.³³

IMMUNOFLUORESCENCE METHODS

Indirect immunofluorescence (IF) is the technique most commonly used in clinical laboratories to screen for specific antibodies that react with cellular antigens. IF is more sensitive than immunodiffusion methods and faster to perform. Its increased sensitivity enables the detection of human antibodies in concentrations less than 0.1 $\mu\text{g/mL}$. The technique is semi-quantitative, with results expressed in titers, and is readily adaptable to the detection and measurement of many clinically important antibodies.³⁴

IF tests are performed by incubating diluted patients' sera with thin sections of animal or human tissues or cultured cells that have been fixed chemically to allow intracellular penetration of specific antibodies. After incubation, unbound antibodies and serum proteins are washed off the slide and a second-stage, fluorochrome-conjugated anti-human immunoglobulin of desired specificity, is pipetted onto the substrate. Reagent antibody binds to any specific antibodies that have been captured by antigens in the substrate. Depending upon the specific test application, a fluorochrome-labeled anti-human immunoglobulin reagent can be chosen that reacts with any or all of the prevalent isotypes of human immunoglobulin, including IgG, IgM, and IgA. Bound anti-human immunoglobulin antibody is visualized by use of a fluorescent microscope. Incident light at a wavelength optimal to excite the fluorochrome is directed at the substrate slide, and light emitted by the fluorochrome is isolated by appropriate filters and transmitted to the microscope objective, where it can be visualized.³⁵ The presence of specific antibodies is indicated by fluorescence of the tissue or cells on the substrate slide.

The accurate performance of IF testing for specific antibodies requires careful attention to quality control of the test specimen, substrate slides, and fluorochrome-conjugated anti-human immunoglobulin antiserum. Sera from fasting patients are optimal for testing, as lipemic or hemolyzed sera may produce increased background fluorescence. In addition, each assay must include known negative- and positive-control sera. Long-term quality control requires comparison testing of successive lots of substrate slides with known negative- and positive-control sera to insure that there is minimal nonspecific binding of human immunoglobulins in the negative sera and comparable binding of specific antibodies, defined by similar endpoint titers (plus or minus one dilution), for the positive-control sera. Successive lots of

CLINICAL PEARLS

ASSESSMENT OF SPECIFIC ANTIBODIES #2

- >> Tests for the detection of specific antibodies are useful for diagnosis in patients with autoimmune diseases, immune mediated inflammatory diseases, immediate hypersensitivity diseases and infectious diseases.
- >> Most tests for specific antibodies are semi-quantitative.
- >> Repeated tests for specific antibodies are not recommended for following the clinical course of most allergic diseases and many autoimmune diseases.
- >> Clinicians must use caution in interpreting the results of antibody tests, as differences in analytical methods can be associated with significant differences in the diagnostic reference values for particular tests.

anti-human immunoglobulin antisera are also compared to ensure reproducibility and analytical sensitivity. Anti-immunoglobulin reagents are characterized in terms of their antibody to total protein content, fluorochrome to protein ratio (typically in the range of 3 molecules of fluorochrome per mole of protein), and the dilution of reagent antiserum that yields maximal specific to nonspecific fluorescence, as demonstrated with well-characterized positive- and negative-control sera.³⁶ In most IF assays it is also desirable periodically to test a weakly reactive, positive-control serum to ensure that there has been no loss of analytic sensitivity from storage of the substrate slides or fluorochrome-conjugated antiserum. IF is routinely used in clinical laboratories to detect and measure antibodies associated with immune-mediated inflammatory diseases and antibodies to some bacteria and spirochetes in infectious diseases.

It is useful here to point out the relative advantages and disadvantages of this technique compared to ELISA methods as discussed below. IF has a long history of use in clinical laboratories and an established base of clinician users. Most physicians are familiar with IF test reports, which include reference ranges expressed as titers accompanied by comments about the pattern or morphologic appearance of fluorescence observed microscopically.³⁷ In addition, IF is suitable for use in both small and large laboratories, provided there are trained personnel available to perform the test and interpret the appearance of slides. For certain applications, one substrate slide can be used to detect several different antibodies simultaneously, e.g., tests for antinuclear antibodies and mitochondrial antibodies can be performed on the same substrate. Disadvantages of the IF method include the time required to perform endpoint titrations of positive sera, subjectivity in the interpretation of fluorescence morphology, and the need for highly trained technologists to perform the test. Nevertheless, it is worth noting that fluorescence microscopy remains useful for the discovery of autoantibodies, e.g., the recently described autoantibodies in patients with neuromyelitis optica.³⁸ IF can also be adapted to create novel test substrates for the clinical laboratory by transfecting cell lines with genetic material that codes for autoantigens of clinical interest e.g., a recently developed test for autoantibodies to proteinase 3 uses transfected human basophilic leukemia cells.³⁹

Secondary antibody conjugate

Fig. 96.8 Enzyme linked immunosorbent assay (see text for explanation).

IMMUNOMETRIC ASSAY METHODS

Immunometric methods, including ELISA, are widely used, versatile analytical systems for the detection and measurement of specific antibodies. These methods make use of reagent antigens immobilized on solid phases (immunosorbents) to capture specific antibodies from patients' specimens. Specific antibodies bound to the immunosorbent in the first stage of the assay are detected in the second stage by incubating with a polyclonal or monoclonal anti-human immunoglobulin antibody labeled with an enzyme or fluorophore. In the final stage of the assay, the amount of labeled second-stage antibody that has been bound to the immunosorbent is determined by measuring a colored or fluorescent product generated by the enzyme label or fluorophore (Fig. 96.8).

Immunometric methods offer several advantages that account for their popularity. A variety of methods have been developed to couple antigens covalently or noncovalently to solid-phase immunosorbents; and each of the principal chemical classes of antigen mentioned previously, including some haptens, has been used as an immunosorbent. Antigen immunosorbents can be prepared from crude antigen mixtures for use in screening tests e.g., the microtiter plate ELISA for antinuclear antibodies, or from highly purified antigens for use in the measurement of marker autoantibodies.³⁶ Immunometric methods are more sensitive than precipitin or agglutination techniques and are similar in sensitivity to IF. Analytical sensitivity is in the range of 1–10 ng of antibody protein/mL, which is adequate for measurement of specific antibodies of all human isotypes and subclasses, including IgE and IgG subclasses. The enhanced analytical sensitivity of immunometric assays is largely a result of amplification of the signal produced by the binding of labeled, second-stage anti-immunoglobulin antibody. As noted above, the second-stage antibody is typically labeled with an enzyme or fluorophore. Commonly used enzyme labels, such as alkaline phosphatase, generate many moles of measurable product for each mole of second-stage antibody bound to the immunosorbent, and reagent fluorophores emit light that can be counted to a predetermined endpoint. The analytic sensitivity of immunometric methods is limited primarily by the ratio of specific to nonspecific binding of immunoglobulin in the first stage of the assay.^{13, 37} Immunosorbents with low levels of nonspecific binding afford maximum analytical sensitivity.

The most common immunometric assay for specific antibodies is the ELISA. In a typical ELISA, antigen is adsorbed noncovalently to the wells of a polystyrene microtiter plate. Different types of plates have been developed to maximize the adsorption of different chemical classes of antigen, including proteins and glycoproteins, phospholipids and nucleic acids, and to minimize nonspecific binding of immunoglobulins. ELISA methods can be used to detect specific antibodies qualitatively, or to make semi-quantitative measurements of specific antibodies by use of a standard curve calibrated in arbitrary units. For qualitative applications, the absorbance in wells incubated with an unknown (e.g., diluted patient serum) is compared to a calibrator that contains a low concentration of antibody. The absorbance of the calibrator is typically at least four times the background level. Positive results are indicated by absorbances significantly greater than the negative control and at least as great as the calibrator. In semi-quantitative applications, the absorbance in wells that contain an unknown specimen is compared to a standard curve prepared by plotting the absorbances of several calibrators. In either application, positive and negative control sera must be run with each assay to ensure that all steps in the procedures have been performed properly. There are limitations on the accuracy and precision of semi-quantitative tests performed by ELISA. Microtiter ELISA methods are inherently quite variable, and inter-assay coefficients of variation for positive sera may exceed 15%. In addition, the standard curve of absorbance versus antibody level is usually nonlinear. Consequently, even though results are reported on a continuous numerical scale in units, the results must be considered semi-quantitative. Results are often interpreted as falling within ranges, e.g., negative, borderline, weakly positive and strongly positive, with each category defined by a range of values expressed in units. Truly quantitative applications of the basic ELISA method are less common. These methods require calibration based on reference preparations that contain known concentrations of the antibody of interest, e.g., WHO Wo/80 for dsDNA antibodies.⁴⁰

As noted above, the most common ELISA method is performed in polystyrene microtiter plates in which an antigen is adsorbed noncovalently to the plate. In other applications, antigen may be coupled covalently to a solid phase. This is particularly common with allergen immunosorbents used to test for specific IgE antibodies (Chapter 100).⁴¹ The principal advantages of covalent coupling are that the antigen immunosorbents are stable indefinitely, and successive lots can be characterized in terms of the amount of antigen coupled per gram of solid phase, and by the capacity to bind antibodies from well-characterized positive control pools.

Given the large number of commercially available, US FDA-approved ELISA assays for antibodies, it is useful to point out the responsibilities of the manufacturer and end-user for validating the performance of these assays in the clinical environment.³⁶ It is generally accepted that the manufacturer is responsible for providing accurate information about the following parameters: expected values of test results in various populations, e.g., blood donor normals and certain relevant clinical groups; analytical assay performance, e.g., accuracy, precision, analytical specificity and reportable range of results; stability of the reagents; and quality control parameters to assess the validity of each test run. The end-user is responsible for validating the analytical performance characteristics mentioned above, and for establishing reference ranges appropriate to the clinical situations in which testing is likely to be performed. This latter point may be difficult to achieve, and clinical reference

ranges may be based on peer-reviewed published clinical studies when it is not possible to conduct studies with clinical specimens obtained locally.

■ EMERGING ANALYTICAL CONCEPTS: PROTEOMICS, AND MICROARRAY AND MULTIPLEX TESTING FOR ANTIBODIES ■

PROTEOMIC METHODS

Analytical methods now applied to the qualitative analysis and measurement of proteins include liquid chromatography (LC) techniques and mass spectrometry (MS).^{42, 43} Test methods that employ these techniques are regarded as the methods of choice for several analytes routinely measured in clinical laboratories, including drugs, drug metabolites, and steroid and peptide hormones.^{44–46} However, for routine measurement of most proteins, including immunoglobulins, immunoassay techniques such as nephelometry and immunometric methods are preferred. The matrix of blood plasma is very complex and may cause artifacts in the measurement of proteins by chromatographic methods. A common problem is suppression of the analytical signal in chromatographic assays which results in low signal-to-noise ratios. Improved analytical sensitivity and specificity for clinically relevant protein analytes has been accomplished by immunoaffinity chromatography and by immunosubtraction techniques.⁴³

An application of advanced proteomic techniques that has gained acceptance in recent years is the analysis of therapeutic antibodies. Monoclonal antibodies are now widely used as therapeutic agents to treat several immune-mediated and autoimmune diseases. For example, antibodies to tumor necrosis factor (TNF) are used to treat rheumatoid arthritis and inflammatory bowel diseases (Chapters 52 and 74).

The pharmaceutical industry standard for therapeutic monoclonal antibodies is to have the purest immunoglobulin with no contamination with other variants. C-terminal modification of the heavy chains with variable numbers of lysines in these drugs is a common structural variation during the manufacturing process and demands careful analysis.⁴⁷ Using capillary isoelectric focusing chromatography, these variants can be readily separated and analyzed, as shown in Figure 96.9A.

Carbohydrate modifications are also known to influence the function and thermodynamic stability of immunoglobulins. Carbohydrate moieties on immunoglobulins can be analyzed using a variety of techniques, such as capillary electrophoresis chromatography and MS spectrometry.⁴⁸ An example of such an analysis is shown in Figure 96.9B.

Chromatography and mass spectrometry methods have been reported to have good precision, linearity, and accuracy. We anticipate that these methodologies will gain acceptance for the analysis of intact immunoglobulins. The methods are rapid, can be automated, and require minimal sample preparation. It is predicted that multidimensional liquid chromatography, e.g., LC-LC-LC-MS, will become a routine analytical tool in the manufacture and quality assessment of reagents. It is likely that improvements in separation technologies will make it possible to lower the manufacturing costs of antibody production and significantly improve the quality of the clinical assays in routine laboratories.

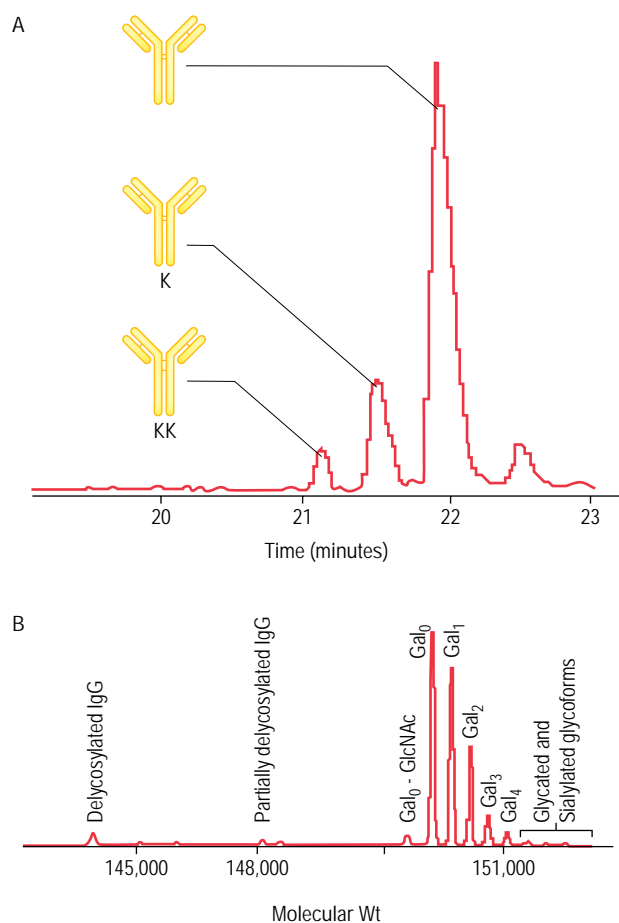

Fig. 96.9 Identification of the C-terminal lysine (lys) variants of an antibody (A) and analysis of carbohydrate modified antibodies (B). (A) Capillary isoelectric focusing separates O-Lys and -Lys fractions of an IgG antibody. (B) Glycated immunoglobulins have been analyzed using MS. Deconvoluted mass spectra of intact immunoglobulin containing low levels of completely deglycosylated, as well as partially deglycosylated species (with one deglycosylated and one glycated heavy chain), and typical IgG glycoforms are shown.

SIMULTANEOUS DETECTION AND MEASUREMENT OF MULTIPLE ANTIBODIES

New technologies for the simultaneous detection and measurement of multiple antibodies include microarray methods and multiplex immunoassay.^{49, 50} Both require that large amounts of data be acquired and analyzed rapidly, which is now possible using digital signal processing technology. Microarray methods consist of multiple simultaneous, qualitative or semi-quantitative immunoassays using activated silica microchips or nitrocellulose paper coated in individual microdots with antigens of interest. This technique has been used in research applications to detect IgE antibodies to both crude and recombinant allergens, and to identify IgG antibodies that react with nuclear antigens or tumor-associated peptides. Binding of antibodies is detected as in a conventional

immunometric assay by the use of anti-immunoglobulin antibodies conjugated with an enzyme or fluorophore. Bound anti-immunoglobulin antibody is visualized by scanning the microarray in a fluorescent microscope or by densitometric scanning of antigen immunodots. Preliminary data indicate that microarrays display good sensitivity; nanogram quantities of Ig can be detected reliably; and they require very small (nanoliter) volumes of test specimen. Microarray systems also can be automated, thus making it possible to test large numbers of samples. Disadvantages of current microarray methods include relatively high analytical variability compared to conventional immunometric techniques and possible interference in detecting antibodies of one isotype due to competition from another isotype. Enhanced susceptibility to interference results from the use of very small quantities of antigen in immunometric microarray systems compared to conventional immunometric assay systems.

Multiplex immunoassay analysis offers another approach to the simultaneous detection of multiple antibodies. Several US FDA-approved multiplex immunoassays are currently available for semi-quantitative measurement of autoantibodies associated with systemic rheumatic diseases, celiac disease and antibody-mediated vasculitides; and quantitative multiplex immunoassays have been described to measure IgG antibodies to bacterial antigens, including up to 23 different *Streptococcus pneumoniae* serotypes. The principle of one multiplex immunoassay is illustrated in Figure 96.10. Polystyrene microspheres are impregnated with varying proportions of two different fluorescent dyes to create a family of microspheres, each with a unique fluorescent signature. Individual microspheres are then coupled covalently with reagent antigens. Different coupling reactions can be used to synthesize protein, nucleic acid or polysaccharide-coupled microspheres. Individual microspheres coupled with different antigens, e.g., individual extractable nuclear antigens in the test for ENA antibodies, can be mixed in a single tube to create an immunosorbent cocktail capable of binding several different antibodies simultaneously. After incubating with a test specimen, standard or calibrator, the microspheres are washed to remove unbound immunoglobulin and an anti-immunoglobulin antibody labeled with another fluorophore is added. The microspheres are then aspirated and separated in a flow cell, where they are illuminated with lasers that simultaneously identify each microsphere by its fluorescent signature and detect antibody bound to the surface by measuring the second fluorescent signal. The ability to measure multiple antibodies simultaneously allows the user to identify an antibody 'phenotype' for each specimen based on the presence of several different antibodies. With this methodology it is also possible to sample specimens in a random access mode rather than creating batches of specimens, and all tests are performed using the same data reduction. It is likely that multiplex immunoassay testing will gain wide acceptance in laboratories that process large numbers of specimens and offer a large repertoire of tests.

ASSESSMENT OF LABORATORY PERFORMANCE

Given the wide variety of analytic methods available to perform laboratory tests for immunoglobulin proteins and antibodies, clinicians and laboratories need a source of information with which to judge the performance (sensitivity and specificity, and market penetrance or acceptability) of the methods they have access to. Much information can be

Fig. 96.10 Multiplex cytometric analysis for antibodies. See text for explanation.

found from the results of federally mandated laboratory proficiency testing programs. The US Clinical Laboratory Improvement Amendment of 1988 (CLIA88) established a single set of federal standards that apply to laboratories testing human specimens.⁵¹ Periodic proficiency testing is a mandatory part of this program. Data from large inter-laboratory proficiency testing programs often include results from hundreds of different laboratories. These data are useful to indicate the performance of each individual laboratory compared to the entire group of laboratories, or of peer laboratories that use the same analytic methods. Proficiency surveys often reveal significant differences for clinically important analytes that may exist among otherwise similar analytical methods.

Flow cytometry

Thomas A. Fleisher, João Bosco de Oliveira

97

Flow cytometry has become a standard laboratory tool in the evaluation of hematopoietic cells, including the identification of lymphocyte populations and subpopulations, a method referred to as immunophenotyping. The clinical application of this technology has been facilitated by the development of instruments and data analysis systems suitable for routine use in diagnostic laboratories. In addition, the expanded range of monoclonal antibodies specific for lymphocyte (and other hematopoietic cell) surface antigens directly conjugated to a number of different fluorescent indicators (fluorochromes) provide an extensive panel of reagents that facilitate multicolor studies.

The clinical needs that drove this technology relate to the emergence of absolute CD4 T-cell counts as a critical measure for disease assessment and follow-up in patients infected with the human immunodeficiency virus (HIV). Flow cytometry applied in the monitoring of HIV infection was followed by the routine application of cell characterization by flow cytometry in the evaluation of lymphoproliferative disorders, and more recently in the study of immunodeficiency disorders as well as other immune-mediated diseases.

The assessment of cell surface characteristics is now often coupled with the evaluation of intracellular parameters, including the detection of specific intracellular proteins including cytokines, and the identification of changes linked to cellular activation and apoptosis. Intracellular flow cytometry also can be applied to evaluate cell cycle status (i.e., G_0 – G_1 , S, G_2 –M) based on DNA staining useful in evaluating tumor cells and assessing the *in vitro* lymphocyte response to various stimuli. Functional testing of lymphocytes can also be performed with cell tracking dyes that allow quantification of the rounds of cell division. Finally, characterization of antigen-specific T cells associated with normal and/or abnormal immune responses in association with disease states or following immunization can be accomplished using multimer technology and intracellular cytokine detection following antigen exposure.

This chapter focuses on the basic concepts of flow cytometry, including instrument characteristics, data management, lymphocyte gating and directed use of test reagents. In addition, a brief overview of intracellular probes, cell activation studies, cell cycle analysis, apoptosis detection and multimer technology is provided, focusing on the appropriate application of these approaches as well as their limitations.

INSTRUMENTATION

The basic components of a flow cytometer, as shown in Figure 97.1, include the illumination source, optical bench, fluidic system, electronics and computer.¹ Illumination in standard clinical instruments is generated by two air-cooled lasers, each of which provides a specific monochromatic light source (e.g., an argon laser generates a 488 nm wavelength [blue] beam and a helium neon [HeNe] laser generates a 633 nm wavelength [red] beam). The point where the light illuminates the cell in analytical instruments occurs within a flow cell, whereas in cell sorters the beam intersects cells flowing as a stream in air. The optical bench contains lenses that shape and focus the illumination beam to ensure consistent excitation energy at the point of analysis. The illumination of a cell generates both nonfluorescent and fluorescent signals that are collected and measured by optically coupling the signal to a detection system consisting of filters linked to a photodetector. The filters are chosen to allow the nonfluorescent signals to be measured at the same wavelength as the excitation signal (e.g., 488 nm), whereas those for the fluorescence channels are linked to the emission signals of specific fluorochromes (e.g., green, orange or red; see Fluorochromes).

The fluidic system lies at the heart of a flow cytometer and consists of isotonic sheath fluid that moves the sample stream containing the cells. This is accomplished by injecting the cell sample into the moving sheath fluid, establishing a hydrodynamically focused single-file flow of cells that move through the analysis point while maintaining the cell stream in a constant, central location.² The centrally focused cell stream ensures that the illumination of all cells is virtually equivalent. Thus, the difference in magnitude of the emission signal generated from each cell reflects biologic differences between the cells (not the result of variation in the illumination energy). The use of hydrodynamic focusing has the additional advantage of producing little or no change in cell shape, although it may have an effect on cell orientation. The consistency in maintaining cell shape makes it easier to distinguish 'architectural' differences between specific leukocyte types (see Gating).³ The choice and arrangement of the filters allows for the simultaneous evaluation of multiple colors (parameters) for each cell, and a recent report described a modified clinical instrument that was capable of evaluating 17 colors simultaneously from each cell contained in the sample.⁴ Thus,

Fig. 97.1 Simplified design of a flow cytometer with one illumination source (laser) set up to collect five parameters. These include the two nonfluorescent parameters (blue light) forward and side scatter, as well as three fluorescent parameters, green (FITC), orange (PE) and red (PerCP) light.

a flow cytometer provides a platform with the capacity to assess multiple pieces of discrete information (parameters) generated from each individual cell contained within a large number of cells present in the test sample, and these are typically accrued at rates of 1000–2000 (or more) cells per second.

The internal electronics in the flow cytometer provide the system for converting analog light signals (photoelectrons) received at the photodetectors into digital signals for acquisition and storage in a computer. The intensity of these converted signals is measured on a relative scale that is generally set in either 256 or 1024 equal increments (referred to as channels) for display and analysis. A number of specialized analysis programs are available and results are depicted graphically as a single-parameter histogram displaying specific light (fluorescence) intensity (x -axis) versus cell number (y -axis) (Fig. 97.2). Two-color (parameter) studies can be evaluated with a pair of histograms (one for each color) or with a single (dot or contour) plot displaying both parameters (Fig. 97.3).

Specialized computer software enables data analysis, which in immunophenotyping studies is typically directed at defining cell subpopulations based on the presence or absence of specific antibody binding. Cell cycle analysis evaluates fluorescence intensity as a measure of cellular DNA content. Most programs enable the operator to evaluate the number of events, percentage of events, mean and/or median channel fluorescence, and selected statistical measures for each identified cell, and these are aggregated into specific populations and/or subpopulations of cells. The mean or median channel fluorescence is a measure of fluorescence intensity and can be used to determine the mean or median number of antigen molecules per cell compared to fluorescence calibration standards.⁵

The evaluation of clinical immunophenotyping data usually involves establishing criteria for the boundaries between negative or unstained cells and positive (stained) cells. This is a very common technique used in clinical laboratories that provides relatively consistent criteria for negative versus positive cell discrimination. When dealing with DNA staining, a consistent cellular source of DNA (e.g. chicken erythrocytes) should be used as an internal reference for evaluating DNA content and cell cycle distribution.

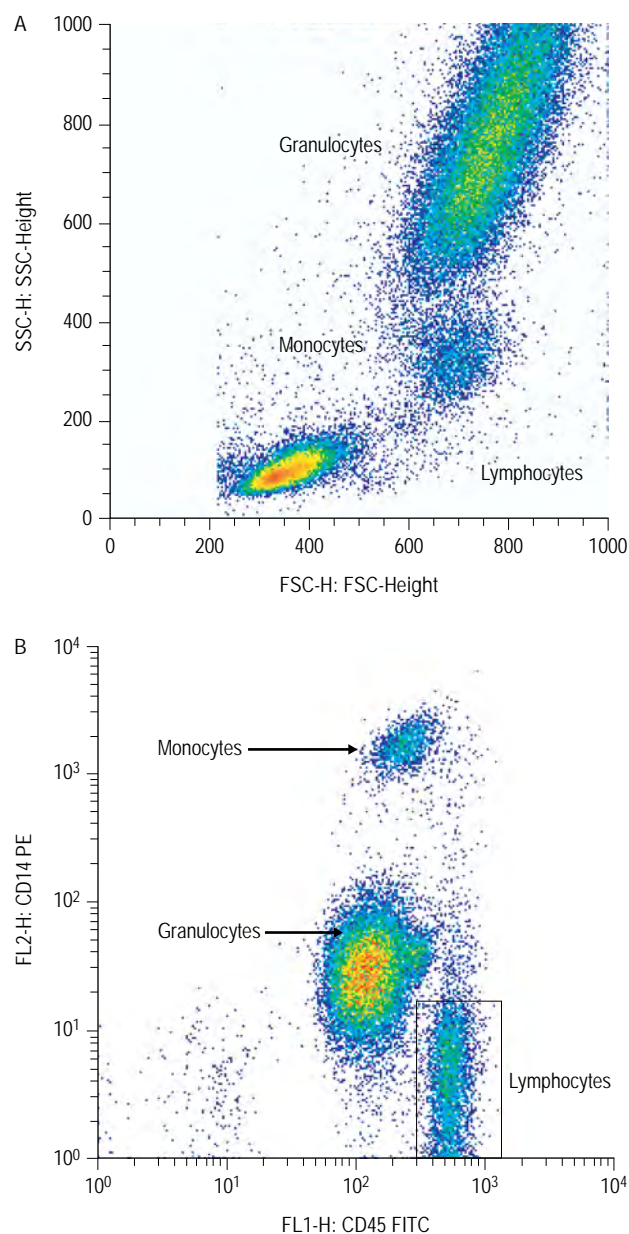

Fig. 97.2 (A) Forward- and side-scatter dot plots on a lysed whole blood sample, demonstrating the basic three-part leukocyte differential with lymphocytes, monocytes and granulocytes. (B) Dot plot with CD45/CD14 gating reagents showing the fluorescence distribution of all the three leukocyte types identified to include lymphocytes, monocytes and granulocytes, as well as a small number of nonlysed red blood cells and/or debris.

Fig. 97.3 Single-parameter histogram for CD3 expression on lymphocytes demonstrating the negative non-T-cell population (autofluorescence and nonspecific antibody binding) and a positive T-cell population. Integrating the area under each curve would provide the numbers and percentage of cells present in each respective subpopulation.

FLUORESCENCE REAGENTS

Standard monoclonal antibody reagents for clinical use are typically directly conjugated to a fluorochrome, a dye that absorbs and emits light of different wavelengths resulting from the energy lost during the return of excited electrons to their ground state.⁶ Thus, the emitted light has a longer wavelength (lower energy) than that of the excitation beam. Direct staining involves the use of directly conjugated reagents, whereas indirect staining involves an unlabeled primary monoclonal antibody followed by a wash step and the addition of a fluorochrome-conjugated antibody reactive with the first antibody (e.g., goat anti-murine immunoglobulin when using a murine monoclonal antibody as the primary reagent). The direct method is technically easier and more readily adaptable to multicolor studies, but the indirect method may be more sensitive (although it often has higher background 'noise'). The three most commonly used fluorochromes in immunophenotyping when using an instrument with a single argon laser (488 nm excitation beam) are fluorescein isothiocyanate (FITC), phycoerythrin (PE), and peridinin chlorophyll protein (PerCP), which emit green, orange and red light, respectively. In addition, an alternative third color (red) has been developed based on energy transfer using one fluorochrome (e.g., PE) to provide the excitation energy (light) for a second fluorochrome (e.g., a cyanine dye such as Cy5) that is the source of emitted light. There are now a number of additional standard fluorochromes and energy transfer based fluorochrome conjugates available to extend the number of colors per study. Most of the current clinical instruments have moved to two (or more) air-cooled lasers and collect at least four fluorescence signals; an eight-color, three-laser

clinical instrument has recently been marketed. The fluorescent signals are usually complemented by collecting two nonfluorescence signals (forward and side scatter). The number of events (cells) analyzed typically ranges from 10 000 to 20 000 in routine clinical studies, but must be increased when evaluating very small subpopulations of cells in order to produce statistically relevant data such as would be necessary in rare event analysis.

Studies of intracellular parameters require the reagents to traverse the cell membrane and gain entry to the cell. This is typically accomplished by cell fixation and permeabilization. Depending on the target area within the cell, an additional step may be required to enable entry to the cell nucleus. Activation-induced changes involve probes including calcium-sensitive dyes (e.g., fluo-3), glutathione-sensitive dyes (e.g., monochlorobimane) and H₂O₂-responsive dyes (e.g., dihydrorhodamine 123).^{7, 8} DNA content can be assessed with dyes that intercalate double-stranded DNA and RNA, including propidium iodide and ethidium bromide.⁹ In addition, there are ultraviolet-excited dyes that are highly specific for DNA, including Hoechst 33258 and 4,6-diamidino-2-phenylindole (DAPI); acridine orange is used for simultaneous staining of DNA/RNA.

One recent exciting advance in the field of fluorescent labeling of molecules was the development of fluorescent semiconductor nanocrystals, named quantum dots.¹⁰ Quantum dots are usually composed of a CdSe core coated with a layer of ZnS. Quantum dots have a broad absorption spectrum and a sharp, discrete emission spectrum, which varies according to their core size. This means that quantum dots of different sizes (and consequently of different emission spectra, or 'colors') can be excited with a single light source, such as UV light, allowing simpler multiplexing. In addition, quantum dots have high quantum yield, high molar extinction coefficients, high photobleaching resistance, and extraordinary resistance to photo- and chemical degradation. These qualities make them perfectly suitable for use in biological studies, including intracellular *in vivo* imaging, fluorescence resonance energy transfer (FRET) analysis, and dynamic imaging of single proteins for longer periods.

IMMUNOPHENOTYPING

GATING

The proper assessment of specific cell types within a mixture requires initial identification of lineage-specific cells, an approach referred to as gating. In practical terms, immunophenotyping focused on lymphocytes requires minimization of the nonlymphocytes included in the evaluation, and this is accomplished by lymphocyte gating. The standard sample for clinical studies is anticoagulated whole blood, and directing the study to lymphocytes requires elimination of the great majority of nonlymphocytes from the collected data, such that the percentage of a specific cell subpopulation is an accurate measurement. Without gating the data can also be negatively affected by co-expression of surface antigens on different cell lineages (e.g., CD4 is found at differing densities on lymphocytes and monocytes). In addition, nonspecific binding of monoclonal reagents through Fcγ receptors and the level of cytophilic human immunoglobulin varies between cell types, making appropriate gating crucial to generate valid data. These techniques are also used to focus the evaluation on other hematopoietic cells, including monocytes, granulocytes, eosinophils, erythrocytes and platelets.

Initial gating to focus on a specific leukocyte population typically involves using the two nonfluorescent parameters, forward angle

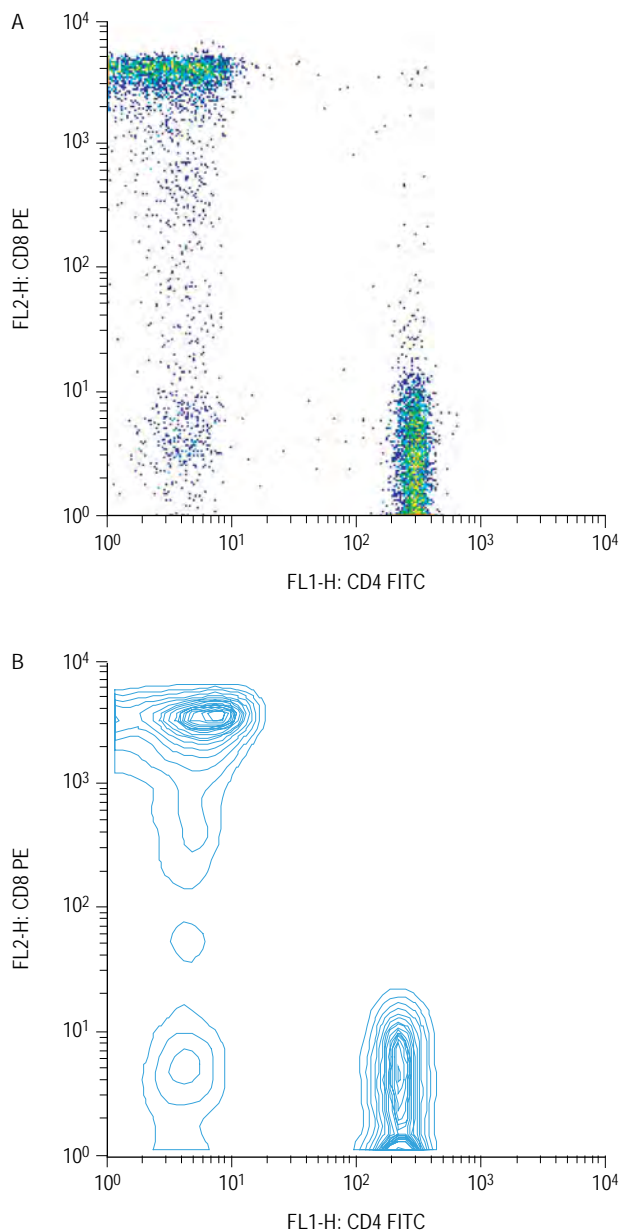

Fig. 97.4 Examples of (A) dot and (B) contour displays based on the same two-color data. Both techniques enable simultaneous evaluation of both parameters in this case evaluating the expression of CD4 and/or CD8 on CD3⁺ T cells. These plots identify four populations of cells: those expressing only CD 4 or CD8, those expressing both CD4 and CD8 (virtually absent) and those expressing neither CD4 nor CD8 (double-negative T cells).

KEY CONCEPTS

GATING

- >> Method to define cell population of interest
- >> Typically performed using forward and side scatter
- >> Should be confirmed with gating reagents (CD45 and CD14 for lymphocytes and monocytes)

(low angle, FSC) and side (90°, SSC) light scatter (Fig. 97.4A).³ Forward scatter is a reflection of cellular cross-sectional area (direct relationship to cell size) and refractive index, whereas side scatter is an indication of cellular granularity and surface irregularity. The combination of these two nonfluorescent parameters provides a three-part differential that distinguishes between normal lymphocytes, monocytes and granulocytes (in the absence of contaminating red blood cells and platelets). As can be seen in Figure 97.4A, lymphocytes have the lowest forward and side scatter, monocytes have higher forward and side scatter, and granulocytes have the greatest side scatter. In most circumstances this method is effective in distinguishing a relatively pure population of lymphocytes. However, the presence of nucleated red cells, large platelets or other particulate debris can produce contaminating events (cells) within this 'lymphocyte gate.' Furthermore, malignant lymphoid cells may not fit into the previously outlined standard light scatter patterns.

A method to confirm the integrity of the light scatter-based lymphocyte gate uses the directly conjugated monoclonal reagents CD45 and CD14.¹¹ These 'gating reagents' more accurately identify the three-part differential. Lymphocytes have the highest level of CD45 binding but are negative for CD14; granulocytes have a lower level of CD45 binding and an intermediate level of CD14 expression; and monocytes have high levels of both CD45 and CD14 expression (Fig. 97.4B). Importantly, nonleukocytes, including erythrocytes and platelets, are negative with both reagents. In addition, malignant leukocytes that have characteristics of early precursor cells often have altered CD45 and/or CD14 expression. Gating reagents provide a reliable means of checking the light scatter-based lymphocyte gate for the frequency of nonlymphocytes within the gate and the extent of lymphocyte exclusion from the gate. Guidelines for an acceptable degree of contamination within the lymphocyte gate, as well as the level of lymphocyte exclusion, are contained within the US Clinical and Laboratory Standards Institute (formerly the National Committee for Clinical Laboratory Standards) guideline for lymphocyte immunophenotyping.¹² In some situations, CD45 has to be included in every analysis tube to refine the gate and prevent cell contamination that cannot be excluded using the standard nonfluorescent parameters (forward and side scatter) for gating.

DATA PRESENTATION

The simplest method for demonstrating flow cytometry data is the single-parameter histogram (see Fig. 97.2), a graphic presentation of cell number on the y-axis versus fluorescence (light) intensity from a single fluorochrome on the x-axis. Integration of curve areas provides the number of cells, and often there are two distinct distributions: one referred to as negative identifies cells that are not bound specifically by the monoclonal reagent, and the second represents cells bound by the

antibody. Negative actually reflects low-level fluorescence resulting from cellular autofluorescence together with any nonspecific binding of the monoclonal reagent(s); the magnitude of the latter varies between different cell types. The interpretation of the data is simplified when there are distinct two cell populations (i.e. negative and positive), whereas evaluation of two overlapping distributions is more difficult.

Multicolor data can be evaluated using a series of single-parameter histograms that consider each fluorochrome independently. However, it is more informative to present two parameters simultaneously using a correlated display (Fig. 97.3), and two-color displays are recommended for clinical flow cytometry.¹³ This approach enables the characterization of four different phenotypes: CD4⁺/CD8⁻, CD4⁻/CD8⁺, CD4⁺/CD8⁺ and CD4⁻/CD8⁻ (using the two reagents anti-CD4 and anti-CD8). When three reagents are used simultaneously, eight different subsets can be identified that would typically be interpreted by first dividing the cells into positive or negative with one reagent, and then evaluating these two defined populations for the remaining two reagents using a two-color approach. The simultaneous use of *n* monoclonal reagents could identify a total of 2^{*n*} subpopulations. The multicolor approach can provide a means to further resolve subpopulations, and has been particularly useful in the evaluation of cellular differentiation, activation and functional correlates, as well as clarifying overlapping cell subpopulations.

A commonly used convention to differentiate between negative and positive cells in a control sample is to establish a marker (discriminator) at the fluorescence histogram channel number such that it includes 98–99% of the negative cells. As previously noted, negative refers to the aggregate of baseline cellular autofluorescence plus nonspecific reagent binding. The latter is generally established by using directly conjugated control monoclonal antibodies of the appropriate class or subclass (e.g., IgG₁, IgG_{2a3}, IgG_{2b} or IgM) that are not specifically reactive with human lymphocyte surface antigens. The negative cell discrimination can be relatively simple to apply unless there is significant overlap between two populations, in which case this approach underestimates the frequency of positive cells.

The level of fluorescence produced by different fluorochromes varies: the brightest of the three standard immunophenotyping dyes is phycoerythrin (PE). This observation has been used to demonstrate that varying the fluorochrome can alter the resolution of antigens expressed at low concentrations. As a general rule, phycoerythrin is particularly suited for evaluating 'dim' positive markers.

It should also be noted that the fluorescence signals emitted by different fluorochromes are not completely separated by the filters. This can lead to signal overlap that is corrected by electronic subtraction of the overlapping signal, a process referred to as compensation. The overlap is particularly significant when using FITC and PE in combination, as FITC produces orange light in addition to the primary green signal emitted by this fluorochrome. The compensation process involves subtraction of the orange signal produced by FITC from the orange signal produced by PE. The availability of tandem conjugates adds another level of complexity, as does four-color flow cytometry, particularly when performed with a single light source. Overlap between fluorochrome combinations must be compensated, and a general approach to successfully accomplish this has been published.¹³

The fluorescence intensity of histogram patterns can be compared between different samples when the same reagent and experimental set-up are used. This enables semi-quantitative comparison of antigen densities between the various cells studied. However, fluorescence data obtained using different reagents generally should not be compared

KEY CONCEPTS

DATA PRESENTATION

- >> Can present cumulative data on more than one parameter for each cell.
- >> Multicolor data presentation may increase cell subpopulation resolution.

because of the variability that results from differences in antibody affinity and fluorochrome-to-protein ratio for the two reagents.

Quality control is a critical component of clinical flow cytometry to ensure optimal results.¹³ This includes monitoring instrument set-up and performance, as well as optimizing sample preparation and reagents and standardizing controls and data interpretation. Quantitative flow cytometry based on a fluorescence standard curve provides quantitative data in units referred to as molecular equivalents of soluble fluorochrome (MESF). When properly constructed standard curves are used, quantitative data for different reagents can be generated and compared.^{5,14} Finally, participation in inter-laboratory proficiency testing surveys, such as the triannual samples provided by the College of American Pathologists (CAP), is an important additional measure to monitor laboratory performance and is mandated in US clinical laboratories by the Clinical Laboratory Improvement Amendment of 1988 (CLIA 88).

METHODS

Whole-blood lysis is the most common technique used for sample preparation and consists of mixing a fixed volume of anticoagulated whole blood (or bone marrow) with one or more directly conjugated monoclonal antibodies, followed by incubation at a designated temperature and time.^{11,15,16} Next the red blood cells are lysed, the sample is washed and then run into the flow cytometer, usually following fixation in paraformaldehyde to reduce the risk of infection. The nonlysed cells remaining include all peripheral blood leukocytes, as well as any nonlysed red cells, platelets and debris. The heterogeneity of the sample necessitates careful lymphocyte gating in order to generate accurate immunophenotyping data. The advantages of the whole-blood lysis method include fewer preparation steps, less sample handling, and a lower likelihood of differential lymphocyte loss. This last point can occur when density gradient techniques are used to prepare mononuclear cells for analysis. Alternative sources of cells (e.g., bronchial alveolar lavage fluid, fine-needle aspirates) can also be evaluated with flow cytometry.¹⁷ Patient studies must be determined with the same methods and reagents as used in the determination of the control ranges to ensure comparability.

The application of control ranges must take into account the fact that significant changes take place in lymphocyte distribution during childhood, as well as in the very elderly.^{18,19} There are also immunophenotypic differences induced by drugs, including tobacco products, such that information on current medications should be obtained whenever possible.²⁰ Other factors can also have an impact on lymphocyte distribution, including race, gender, diurnal variation, and recent or intercurrent infection.²¹

Table 97.1 Selected lymphocyte surface antigens for immunophenotyping

T cells

Pan-T cell: CD3, CD2, CD7, CD5
Major T-cell subset: CD4, CD8
Surface antigens associated with function: CD28, CD38, CD45RA, CD45RO, CD62L
Activation antigens: CD25, CD40L, CD69, CD71, HLA-DR

B cells

Pan-B cell: CD19, CD20, surface immunoglobulin
Major B-cell subset: CD5, CD21
Surface antigens associated with function: CD27, CD40
Activation antigens: CD23, CD25

NK cells

Pan-NK cell: CD16, CD56
NK subset: CD2, CD8, CD57

The choice of immunophenotyping reagents depends on the cells being studied and the question being asked. However, regardless of the specific set-up, the inclusion of a tube with gating reagents (CD45 and CD14) to confirm the integrity of the standard lymphocyte gate is recommended.¹¹ In addition, control reagents should be included to establish the fluorescence intensity of negative cells. Additional important controls include a pan-T cell, B-cell, and NK-cell marker for every sample (Table 97.1) as this provides an internal control, based on the principle that the whole is the sum of its parts. Thus, the total percentage of lymphocytes in the gate determined by the gating reagents should approximately equal the sum of the percentages for T cells, B cells, and NK cells. A technical or biological explanation must be identified when this relationship does not hold. Biological explanations for a significant difference would include the presence of immature or malignant cells that were not identified by standard pan-T cell, B-cell and NK-cell reagents. In addition, if the gating reagents (CD45/CD14) had not been included, contaminating cells (e.g., myeloid precursors, nucleated red blood cells, large platelets) with forward- and side-scatter characteristics similar to those of lymphocytes could not be ruled out. Potential technical problems include reagent or fluorochrome degradation, failure to add a reagent, and a host of others. Evidence of a major technical error should result in repeating the study.

Additional data that can be used for controls depend on the set-up. For example, the availability of multiple antibodies that identify a similar cell (sub)population can serve as a useful check (e.g., total T cells by comparing CD3 and CD5 or CD2; total B cells by comparing CD19 and CD20). In addition, the use of specific reagents in more than one tube enables comparison between the repeat values as a measure of consistency. The application of internal checks should be performed by the flow operator as a simple means of confirming the validity of the data. Insights regarding unusual biological findings may also be uncovered through this type of evaluation (e.g. the presence of an increased population of CD4⁺/CD8[−] double-negative T cells).²²

The challenge in performing immunophenotyping is to accurately identify cells with specific surface characteristics (antigens). As previously noted, the capacity to discriminate cell subpopulations is often enhanced through the directed use of antibody combinations. The typical data generated consist of the percentage of negative versus positive cells when using one reagent, and multiple subpopulations when using more than one reagent. Regardless of the experimental design, it is important to consider not only the percentage of cells within each subpopulation, but also the absolute number of cells. This is most commonly obtained by multiplying the relevant percentage from the flow cytometer by the absolute lymphocyte count obtained using a white blood count and differential. For example, when assaying for CD4 T-cell counts, the percentage of CD4⁺ cells is multiplied by the peripheral lymphocyte count to yield the absolute CD4 count. A potential problem with this approach is the requirement for two separate procedures (i.e., dual platforms) to generate the final result. This introduces the possibility of additive error, based on the inherent errors of the two different methods. It has also fueled a search for approaches that facilitate the performance of both tasks by flow cytometry (i.e., a single platform). One alternative involves the inclusion of a fixed number of fluorescent beads (in a defined volume) in each tube as a reference standard to generate absolute numbers without requiring the use of the complete blood count and differential to generate a lymphocyte count. Regardless of the approach, it is necessary to report both percentages and absolute numbers when immunophenotyping peripheral lymphocytes.

The object of evaluating malignant cells is often to characterize the lineage and differentiation level of the abnormal cells, rather than to quantify subpopulations.²³ The pattern of reactivity combined with fluorescence intensity is often useful in identifying leukemic patterns, whereas the absolute number of cells may not be required. However, flow cytometric detection and quantification of rare abnormal cells can be useful in evaluating for minimal residual disease in lymphoproliferative disorders.

IMMUNOPHENOTYPING STUDIES

The majority of immunophenotyping studies are directed at quantifying specific cell subpopulations, evaluating for the presence or absence of particular surface antigens, identifying the differentiation level of specific cells, determining cell lineage, evaluating for functional correlates based on specific antigen expression, examining for evidence of cell activation, and/or establishing monoclonality.

CLINICAL RELEVANCE

IMMUNOPHENOTYPING STUDIES

- >> Can be used to identify cell subsets, lineage, stage of cell differentiation, state of cell activation, and clonality.
- >> Lymphocyte results should be checked with T cells + B cells + NK cells = 100%.
- >> Immunophenotyping studies are not the equivalent of lymphocyte function studies.

A particular cell subpopulation can be readily quantified with flow cytometry. The evaluation of absolute CD4 T-cell counts has formed the basis for monitoring patients infected with HIV.²⁴ Quantification of CD34⁺ hematopoietic stem cells in donor peripheral blood or bone marrow is used in many cellular reconstitution protocols.²⁵ Subpopulation characterization can also be useful in the evaluation of patients with clinical history and laboratory findings suggestive of immunodeficiency. These studies identify the presence or absence of cells and surface proteins associated with specific functional attributes, but do not assess the actual functional status of the cells. This point is clearly illustrated by the finding of normal B-cell numbers in most patients with common variable immunodeficiency, despite the fact that these patients fail to produce immunoglobulins normally.²⁶ However, changes in the characteristics of the cells present may provide insight into the basis of a disorder, an observation that has been made in some patients with CVID, and provides additional support for heterogeneity of patients with this disorder.²⁷ Because of the limitations of immunophenotyping, it is common practice when evaluating the status of the immune system to test cell function in parallel.

Flow cytometry can be used to test for the presence or absence of a specific cell surface antigen. An example of this type of application is in the evaluation of a patient with a history of recurrent skin infections, delayed wound healing and persistent granulocytosis that suggests a diagnosis of type 1 leukocyte adhesion deficiency.²⁸ This disorder results from a defect in the gene encoding CD18, preventing the expression of three different heterodimeric adhesion molecules each containing CD18 (Chapter 21). This disorder can usually be diagnosed by studying granulocytes (and lymphocytes) for the expression of CD18 (as well as the three isoforms of CD11). Patients often have reduced rather than absent CD18 expression, and the diagnosis can be further confirmed by demonstrating a failure of CD18 (and CD11a, 11b, 11c) upregulation following cell activation.

The directed use of a panel of monoclonal reagents can help address questions regarding the level of cell differentiation. Antibodies that are specific to proteins expressed by early (precursor) cells represent one approach, which would include evaluating for the thymocyte marker CD1, or the pre-B-cell marker CD10 (CALLA). However, many surface antigens are expressed throughout differentiation. Examples of these include CD2 and CD7 found on thymocytes and circulating T cells, or CD19 and HLA-DR found on pre-B cells as well as B cells. Thus the pattern of surface antigen expression can also help distinguish the level of differentiation. Defining the developmental level of a particular cell population or subpopulation is best accomplished using a panel of reagents that span the natural history of the cell lineage. This approach represents the standard for testing leukemias and lymphomas, enabling improved classification of the malignant cells relative to prognosis and therapy. Focusing on the presence or absence of specific antigens also involves evaluating the level of expression. Malignant cells may express antigens associated with different lineages, such that lineage-directed studies can provide insight into shared expression of specific antigens. Additionally, malignant cells may have altered forward- and side-scatter characteristics, as well as diminished or absent CD45 expression.²³ Thus, the approach to gating may have to be modified when studying hematopoietic malignancies.

Issues of monoclonality can be dealt with using flow cytometry when analyzing B cells, and in some circumstances when studying T cells. Normally B cells are a heterogeneous mixture of mutually exclusive κ or λ light chain-positive cells. The distribution of light-chain expression

can be evaluated for clonal excess using a method called the Kolmogorov-Smirnov D value comparison.^{29, 30} Light-chain clonal excess will usually be accompanied by an excess in B cells expressing one particular heavy chain (α , γ , μ or ϵ). The capacity to evaluate T-cell monoclonality by flow cytometry is less definitive and consists of using T-cell antigen receptor β -variable chain-specific reagents looking for evidence of significant over-representation of one β -chain family.

The state of lymphoid activation can be addressed by evaluating for the presence of surface antigens that are either found only on activated cells or are upregulated following activation. These include receptors for specific growth factors (e.g., IL-2 receptor α chain, CD25), receptors for critical elements required for cell growth (e.g., transferrin receptor [CD71]), ligands that are critical for cell-cell communication following activation (CD40 ligand [CD152] on CD4 T cells), and surface antigens that are upregulated as a result of activation (e.g., adhesion molecules, HLA-DR, CD69). In addition, the memory status of both T and B cells can be assessed based on differential surface molecule expression associated with prior antigen encounter. This enables a distinction to be made between naïve T cells that express CD45RA, CD62L and CXCR7 from memory T cells that express the alternative CD45 isoform CD45RO (and varied CD62L or CXCR7, depending on whether the cells are central or effector memory cells).^{31, 32} In addition, memory B cells can be detected by the expression of CD27 and be further divided into isotype switched or nonswitched, based on their pattern of surface immunoglobulin expression.^{27, 33}

INTRACELLULAR EVALUATION

CELLULAR ACTIVATION

Ligand binding and transmembrane signal transduction resulting in cellular activation can be evaluated using flow cytometry. Changes in intracellular ionic calcium concentration (Ca^{2+}) are frequently used to monitor cell activation after ligand binding. These changes are associated with the activation of phospholipase C and protein kinase C. In general, three reagents have been used to measure Ca^{2+} : quin 2, indo-1, and fluo-3. Quin 2 has a low excitation coefficient and is not useful for

flow cytometry; indo-1 requires ultraviolet excitation; fluo-3 can be excited by 488 nm but does not permit ratiometric analysis. Nevertheless, because of its ease of use, fluo-3 is currently the most widely used probe for intracytoplasmic Ca^{2+} evaluation by flow cytometry. Strict attention must be paid to loading conditions, the presence or absence of free Ca^{2+} in the media, experimental temperature, baseline measurements and calibration. This approach can be combined with cell surface marker or cell cycle evaluation.⁷

Intracellular pH changes related to cellular activation also can be evaluated. The most useful probe for pH is SNARF-1.⁷ This probe can be excited at 488 nm and allows for ratiometric analysis with detection wavelengths set for 575 and 640 nm. Glutathione (glutamylcysteinylglycine, GSH) is an important antioxidant generated during cell activation that can be measured by flow cytometry.⁷ The fluorescent probe monochlorobimane is most commonly used for this measurement, but is complicated by the need to determine GSH by an independent method such as HPLC.

Additional approaches to evaluate cellular activation include assessment of intranuclear markers (Ki-67, PCNA) as well as surface proteins that are upregulated following cellular activation (e.g., CD69, CD25, CD71).³⁴ Actual cell division can be evaluated using lipophilic membrane dyes (e.g., PKH26), also referred to as cell tracking dyes, which lose 50% of their fluorescence with each round of cell division.³⁵ This approach has become more common in the clinical assessment of lymphocyte function because of its capacity to evaluate specific lymphocyte subpopulations responding to mitogenic and antigenic stimuli. Lipophilic membrane dyes also can be used to label target cells in cell-based cytotoxicity assays.³⁶

Functional evaluation of cell activation can be accomplished with flow cytometry-directed detection of the generation of phosphorylated intracellular proteins associated with specific activation signals. An example of this is the detection of phosphorylated STAT-1 following interferon- γ stimulation of monocytes, which has been found to be more sensitive than immunoblotting.³⁷ This type of assay requires fixation and permeabilization to allow the entry of the specific reagent, and has now been extended to a number of additional intracellular proteins that are phosphorylated after specific exposure of the cell to specific stimuli. Currently, a number of intracellular signaling proteins that undergo phosphorylation following a specific activation signal can be assessed with flow cytometry using commercially available reagents in kit form.

The assessment of oxidative burst following cell stimulation plays a central role in neutrophil function testing using the hydrogen peroxide-sensitive dye dihydrorhodamine 123. This procedure involves loading the granulocytes with the dye, stimulating with phorbol myristate acetate (PMA), and evaluating for fluorescence by flow cytometry.⁸ This test has proved to be extremely accurate in diagnosing patients with chronic granulomatous disease (CGD) and carriers of X-linked CGD.³⁸ A major advantage is its sensitivity, which allows the detection of one normal cell in a population of 1000 abnormal cells. This makes assessment of oxidative burst a useful tool in following allogeneic granulocyte survival after transfusion into patients with CGD, as well as in evaluating the effectiveness of allogeneic stem cell transplantation and gene therapy in CGD.

INTRACELLULAR CYTOKINE DETECTION

Flow cytometry provides a platform to evaluate cytokine production at the single-cell level using cytokine-specific directly conjugated monoclonal antibodies following fixation and permeabilization of cells.^{39, 40}

This approach allows for the simultaneous detection of two or more intracellular cytokines combined with cell surface markers or other intracellular markers. Important aspects of intracellular cytokine detection include the use of a protein transport inhibitor during activation, the use of proper controls, and the choice of antibodies. As there is little or no spontaneous cytokine production in circulating human lymphocytes, intracellular cytokine detection requires *ex vivo* activation. Initial experience was based on supraphysiological stimulation using PMA and ionomycin, but antigen-specific activation systems have also proved feasible. It should be emphasized that, regardless of the activation method, the duration of activation is an important variable, as individual cells reach maximum cytokine production at different times. In addition, different cytokines have different optimal periods of activation. It is recommended that a proper kinetic profile be established for the biological system or clinical condition being studied.³⁹

To increase the amount of intracellular cytokines, inhibitors of intracellular protein transport, such as monensin or brefeldin, are commonly used and lead to the accumulation of proteins within the cell. Nonspecific binding of the antibody reagents is an issue, as permeabilization allows access not only to the cytokine of interest, but also to other proteins present in much greater quantities than on the cell surface. In addition, fixation further increases nonspecific binding and the use of both a negative control sample, which contains an excess of unlabeled or 'cold' anticytokine antibody, and a subclass-matched control sample provide the optimal control. When the conjugated anti-cytokine is added to the negative control sample it can only bind to other proteins in a nonspecific manner, thereby providing a measure to discriminate between specific and nonspecific binding.³⁹ The use of directly conjugated anti-cytokine antibodies not only simplifies the staining procedure, but also provides the best distinction between specific and nonspecific binding. Because the fixation agent may change the native state of certain epitopes, it is also important when combining cell surface characterization with intracellular cytokine evaluation to use antibodies that recognize antigens after fixation.

One of the main applications of intracellular cytokine detection by flow cytometry has been the study and refinement of the Th1/Th2 paradigm.⁴⁰ It has recently become clear that the regulated secretion of cytokines can be used to study the response of individual T cells to both polyclonal stimuli and specific antigens. Measuring antigen-specific T-cell cytokine expression in response to specific antigen offers a useful alternative to the tetramer-based approach (discussed later) to quantify the frequency of antigen-specific T cells (Fig. 97.5).⁴¹

CELL CYCLE ANALYSIS

In addition to surface immunophenotyping and cytoplasmic characterization, flow cytometry is also used in cell cycle analysis. Propidium iodide (PI) is the most commonly used fluorochrome, owing to its optimal linear DNA-binding capacity in a variety of different cell types. Thus, a single-parameter histogram of DNA content using PI readily permits the determination of cell cycle compartments, expressed as the percentage of cells in G_0 - G_1 , S and G_2 -M (Fig. 97.6A). In addition to these conventional parameters, the presence or absence of aneuploidy can be determined by inspection of the G_0 - G_1 peak and/or use of a DNA index (ratio of abnormal DNA content to a diploid DNA standard). Also, elevation in the S and/or G_2 -M phases can be detected. The optimal display

Fig. 97.5 Two-color dot plots of CD3⁺ T cells evaluated for intracytoplasmic interferon- γ and IL-4 expression. The donor had a positive skin test to PPD and demonstrated a Th1 pattern of cytokine expression (interferon- γ) in response to *Mycobacterium tuberculosis* antigen, with an absence of a Th2 cytokine pattern (IL-4). (Courtesy of Dr Calman Prussin.)

of these data uses a combination of side scatter versus DNA content. Cells observed on the histogram in the area below the level of G₀-G₁ may be undergoing apoptosis.⁴²

It should be noted that several different computer algorithms have been developed to determine the relative proportion of each cell cycle compartment, and the selection of a software program is not a trivial

CLINICAL RELEVANCE

- >> Can be combined with markers of apoptosis.

process. The major instrument manufacturers supply cell cycle analysis programs, and there are also third-party programs available. Generally the optimal program should be capable of modeling two or more aneuploid populations, subtracting debris (particularly if formalin-fixed paraffin-embedded archival material is used) and accurately estimating S-phase cells.^{9,43} The combination of a surface marker and cell cycle has been very useful in differentiating normal cell populations from tumor cell populations.⁴⁴ One example is the use of either anti- κ , anti- λ or B-cell reagents to separate the aneuploid B-cell clone from the remaining normal, reactive B cells in a lymphoid cell mixture. Another uses cytokeratin as a marker to distinguish between the tumor cells and the inflammatory cells that are present.

The other major event that has occurred in cell cycle analysis has been the development of technology using the incorporation of bromodeoxyuridine.⁴⁴ This thymidine analog is used to directly determine the percentage of S-phase cells. Also, when used in kinetic studies it permits a determination of the individual times for the components of the cell cycle and a determination of the growth fraction. Finally, recent developments have resulted in the availability of two anticyclin reagents to evaluate cell cycle transition points in malignant cells.⁴⁵

APOPTOSIS DETECTION

Flow cytometry has become the method of choice for the detection and quantification of cellular apoptosis.⁴⁶ This is due partly to its capacity for rapid assessment of a large number of cells and samples. Many distinct features of an apoptotic cell can be evaluated by flow cytometry based on light scatter, plasma membrane changes, mitochondrial transmembrane potential, DNA content and DNA integrity.

The light-scattering properties of a cell undergoing programmed cell death are the simplest attributes that can be assessed by flow cytometry. Dying cells typically shrink, producing a loss in forward light scatter (FSC) and, despite an initial transient increase in side scatter (SSC), also ultimately demonstrate a decrease in SSC (Fig. 97.6B). The use of light scatter can be combined with cell surface staining to help characterize the dying cells. However, scatter changes alone are not specific to apoptosis, and should be accompanied by an additional characteristic associated with cell death. Live cells have phospholipids asymmetrically distributed in the inner and outer plasma membrane, with phosphatidylcholine and sphingomyelin on the outer surface and phosphatidylserine (PS) on the inner. Early during apoptosis cells lose asymmetry, exposing PS on the outside. Annexin V is a protein that binds preferentially to negatively charged phospholipids such as PS, and directly conjugated annexin V is a useful reagent for the specific detection of apoptotic cells.⁴⁷

Fig. 97.6 (A) Assessment of DNA content as a reflection of cell cycle demonstrating cells in G₁, S and G₂-M phases. (B) Assessment of live versus dead cells based on forward- and side-scatter characteristics. (C) Assessment of cell apoptosis using PI and Dioc6(3) identifying cells that recently initiated apoptosis (early), cells that are dead (late) and cells that are alive (live).

KEY CONCEPTS

PEPTIDE-MHC TETRAMERS

- Useful to assess the number of antigen-specific T cells.
- Can be directed at both CD4⁺ and CD8⁺ T cells.
- Requires information about the antigenic peptide and HLA (MHC) restriction.

Another characteristic of plasma membranes of live cells is that they exclude charged cationic dyes such as propidium iodide (PI) and 7-amino-actinomycin-D (7-AAD). Consequently, only cells in a late stage of apoptosis, with ruptured cell membranes, will take up these dyes. Thus, the combined use of cationic dyes (e.g., PI) with annexin V allow the discrimination between live cells (annexin V negative/PI negative), early apoptotic cells (annexin V positive/PI negative) and late apoptotic cells (annexin V positive/PI positive).

Assessment of mitochondrial transmembrane potential ($\Delta\psi_m$) is yet another technique used to identify apoptotic cells. Cells reduce $\Delta\psi_m$ very early in the apoptotic process, before rupture of the plasma membrane, losing the ability to accumulate potential-dependent dyes such as rhodamine 123, JC-1 or 3,3'-dihexyloxacarbocyanine iodide (Dioc6 [3]). These dyes can also be used with PI to detect cells in the different stages of apoptosis (Fig. 97.6C).

Measurement of DNA content can also be employed to distinguish live from dead cells, as described in the section above (see Cell cycle analysis). This kind of analysis has to be done using a linear scale, not logarithmic, in order to discriminate dying cells from debris. DNA cleavage also exposes OH termini associated with the DNA breaks, and these can be detected via the attachment of fluorochrome-conjugated deoxynucleotides, in a reaction catalyzed by exogenous TdT, a technique called TUNEL.

PEPTIDE-MHC MULTIMERS

In contrast to B cells, direct visualization of antigen-specific T cells *in vivo* has, until recently, been unsuccessful. In 1996, Altman et al.⁴⁸ introduced a novel flow cytometry-based method that enables the direct visualization and quantification of antigen-specific T cells. By generating soluble peptide-MHC multimers, such that multiple TCRs are engaged at the same time, the avidity of these multimeric ligands for the peptide-specific TCR is greatly increased. The methodology involves engineering a biotinylation recognition sequence on the COOH terminus of the extracellular domain of one chain of the MHC molecule that, after combining with a specific antigenic peptide, is bound by avidin or streptavidin. As both avidin and streptavidin have four biotin-binding sites, the result is a tetrameric peptide-MHC complex that serves as a ligand for T cells specific for both the peptide and MHC. Flow-cytometric detection is achieved by labeling streptavidin with a fluorochrome. The major pitfall to this approach is the need to know the antigen-derived peptide and its HLA-restrictions, as well as the HLA type of each subject studied. Since the initial report, an increasing number of tetramer-based studies have appeared. Most have focused on the MHC class I-mediated immune response, in both mice and humans, to a variety of infectious agents, including cytomegalovirus (CMV),⁴⁹ HIV, Epstein-Barr virus (EBV) and others. Since the initial description with class I-restricted recognition, detection of antigen-specific CD4 T cells with tetramers of soluble MHC class II molecules and covalently linked peptide has also been reported.⁵⁰

In addition to demonstrating the feasibility of this approach, the published studies have provided several new insights into the MHC class I-mediated immune response (Chapter 5). For example, it has become clear that the extent of the MHC class I-mediated cellular response is much greater than previously estimated. Furthermore, the extensive proliferation of CD8 T cells during an acute infection is not the result of bystander activation, but rather represents an expansion of antigen-specific CD8 T cells. One possible explanation is that, in contrast to previously used techniques such as the limiting dilution assay, tetramer-based assays do not depend on *in vitro* cell division and survival. Peptide-MHC tetramer assays have also shown promise in the study of the kinetics of

primary and secondary immune responses, as well as in a better understanding of concepts such as immunodominance and clonal exhaustion.

An obviously attractive aspect of this technology is that tetramer staining can be combined with a variety of cell surface and intracellular phenotypic and functional markers. Already there are indications that the phenotype of antigen-specific T cells varies between individuals and between different phases of the immune response. In addition, tetramer-positive T cells can be sorted for further analysis, such as cytotoxicity assays or *in vitro* expansion. The tetramer-based technology has not only proved useful for the study of the immune response to infectious agents, it has also been applied to the study of oral tolerance, autoimmune conditions and tumor immunology. It is likely that this highly sensitive and specific technology and other approaches that define antigen specific responses will find many more applications and will lead to new discoveries and a reassessment of certain existing concepts.⁵¹

CONCLUSION

Flow cytometry has become readily available in clinical laboratories, and its application has moved forward in parallel with significant improvements in instrumentation and the availability of an array of monoclonal reagents. Properly performed, flow cytometry can provide rapid and accurate identification of lymphocyte subpopulations. The primary clinical indications for immunophenotyping remain quantifying CD4 T-cell counts in HIV infection, lineage assignment in leukemias and lymphomas, and assessing CD34 expression to identify stem cells for transplantation. Additional uses include characterizing immunodeficiency disorders, evaluating immune-mediated inflammatory diseases, and assessing patients after organ transplantation. The real utility of these newer applications remains to be fully clarified, and in most settings immunophenotyping does not represent a diagnostic procedure but rather plays a part in the evaluation and understanding of complex disorders and the longitudinal evaluation of immunomodulatory therapy.

It is critical to recognize that immunophenotyping is a means of identifying cells, but it is not directed at cell function. The expansion of flow-cytometric techniques to evaluate intracellular characteristics, assess intracellular changes associated with activation characterize apoptosis and identify antigen-specific T cells is moving this platform into the arena of cell function. These newer approaches are expanding the utility of flow cytometry as a valuable tool for the characterization of immune function.

Assessment of functional immune responses

Jack J. H. Bleesing, Kimberly A. Risma

98

A comprehensive clinical evaluation of the immune system, whether to diagnose immunodeficiency or other immune-mediated disorders, ideally includes both quantitative and qualitative aspects. According to the principle: ‘form follows function,’ important clues to the functional status of the immune system are provided by the assessment of form (quantity), as determined by the cellular phenotype of lymphocytes and other cell populations and by the measurement of secreted/produced factors (complement factors, antibodies, cytokines, etc.).¹ For example, lack of memory B cells, as determined by flow cytometric measurement of CD27 expression on B cells (Fig. 98.1C), can guide appropriate functional testing of the B-cell compartment. This theme of interconnected determination of form and function will be a central thread throughout this chapter. Rather than describing in great detail the technical aspects of individual assays, the emphasis of this chapter will be on providing a general overview in the context of indication and interpretation. For more in-depth discussions on the assays themselves, the reader is referred to other sources, such as *Current Protocols in Immunology*^{1a} and the *Manual of Molecular and Clinical Laboratory Immunology*,^{1b} among others. Most of the assays described in this chapter are performed in highly specialized laboratories that often have a dual clinical/research mission. This dual role has been artificially separated into clinical and research sections in this chapter.

Despite enormous advances in technology, not much has changed in the day-to-day practical assessment of lymphocyte function, as routinely performed in clinical laboratories. In addition, it has been well recognized that certain immunologic conditions defy commonly used tools of laboratory investigation. This may be due to the fact that the “wrong” populations of cells are studied; the method of *in vitro* testing does not appropriately mimic the *in vivo* situation, and other factors. Thus new assays need to make their way into the clinical laboratory to capture these “emerging” disorders. Some of these assays are almost ready for clinical “prime time,” whereas others are still in the early phases of development.

CLINICAL IMMUNOLOGY

GENERAL CONSIDERATIONS

Since the immune system operates in a profoundly intricate matter that is difficult to define by straightforward *modi operandi*, it is generally necessary to assess immunologic function according to pragmatic models

KEY CONCEPTS

BASIC CONCEPTS OF FUNCTIONAL TESTING

- >> Immunologic form follows immunologic function
- >> The right assay(s) for the right clinical scenario
- >> An abnormal result invites several essential considerations:
 - Does it reflect a biologically accurate and reproducible finding (confirmation)?
 - What is its relevance (interpretation; pattern recognition)?
 - What is its significance (further studies, patient care issues)?
 - Is it reflective of disease and/or age (age-appropriate controls)?
- >> With the exception of completely normal and abnormal test results, speculation is invariably involved in data/result interpretation (the gray zone)
- >> *In vitro* assays that provide increasingly detailed information are also increasingly more demanding and prone to variation and artifacts, requiring rigorous quality control measures

or schemes. This approach divides the immune system into compartments, such that essentially every aspect of immune function can be studied through *in vivo*, *ex vivo*, or *in vitro* measurements. Focusing on the lymphoid system, functional assessment of T-, B-, and natural killer (NK)-cell compartments can be separated in phases of activation, and by functional output (Table 98.1). Another approach to dissect the complexities of lymphocyte function is to assay lymphocyte function following various methods of activation to reveal its normal (or abnormal) function (Table 98.2). Finally, functional assays can be distinguished based on whether they test function *in vivo* (measured *ex vivo*), or *in vitro*.

As with all laboratory studies, interpretation of abnormal immunologic studies leads to three basic questions. First, does the abnormality reflect a biologically accurate and reproducible finding? It is important to confirm test results, also paying attention to correct procurement and processing – including labeling – of specimens. Second, what is the relevance of the finding? In other words, what is the underlying basis for

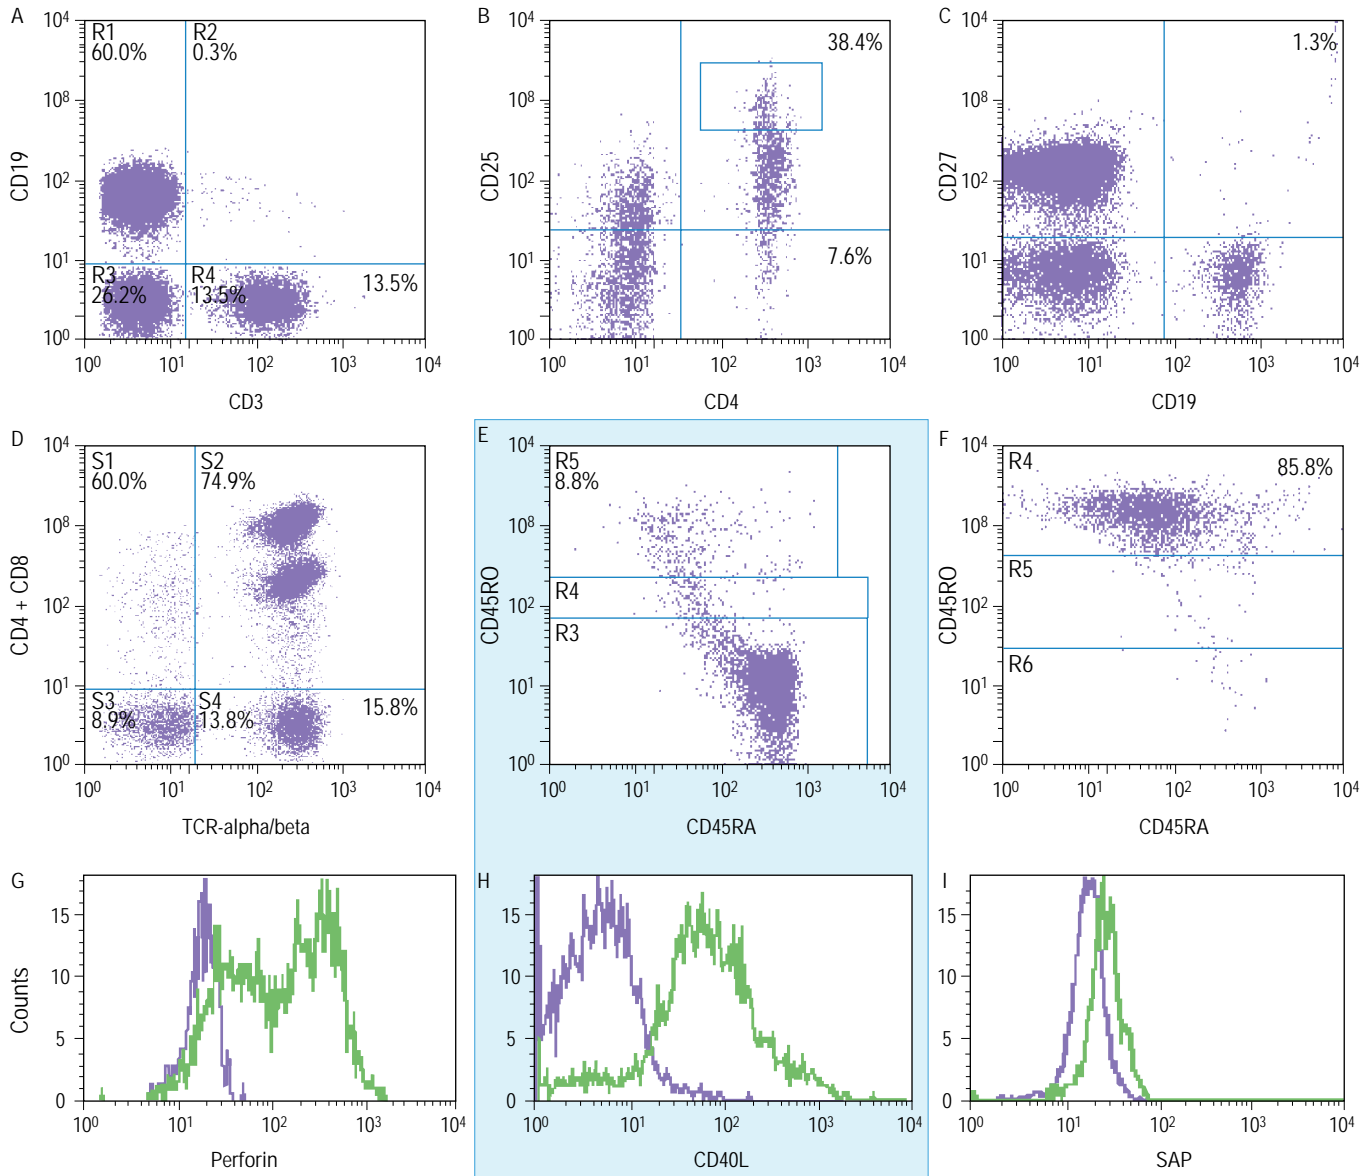

Fig. 98.1 Immunologic form follows immunologic function. Examples of abnormal immunologic form, detected by flow cytometry (dual-parameter dotplots A–F; single-parameter histograms G–I, showing patients in purple and controls in green). **(A)** Reduced T-cell compartment in patient with DiGeorge syndrome (gated on total lymphocytes; 13.5% versus 60–70% of lymphocytes in controls). **(B)** Activated CD25-expressing (CD4⁺) T cells in patient with chronic rejection of orthotopic liver transplantation (gated on total T cells). **(C)** Lack of memory B cells in patient with common variable immunodeficiency (CVID), as determined by CD27 expression (gated on total lymphocytes; 1.3% versus >15% of B cells in controls). **(D)** Presence of T cells expressing the T-cell receptor (TCR)-alpha/beta but lacking CD4 and CD8 in a patient with autoimmune lymphoproliferative syndrome (ALPS, gated on total T cells; 15.8% versus <2% of lymphocytes in controls). **(E)** Lack of CD45RO-positive T cells in young adult with X-linked hyper-IgM syndrome (gated on total T cells, see H for associated functional assay). **(F)** Lack of CD45RA-positive T cells in patient 12 months post bone marrow transplantation (gated on total T cells). **(G)** Lack of intracellular perforin in natural killer (NK) cells (and associated defective NK-cell function) in patient with familial form of hemophagocytic lymphohistiocytosis on the basis of mutations in the perforin gene (FHLH, gated on total NK cells). **(H)** Lack of CD40L upregulation on (CD4⁺) T cells following 4-hour T-cell stimulation (gated on CD8-negative T cells). **(I)** Lack of intracellular Signaling Lymphocyte Activation Molecule (SLAM)-Associated Protein (SAP) expression in (CD8⁺) T cells in patient with X-linked lymphoproliferative disease (XLP, gated on CD8-positive T cells; cytolytic functions were abnormal in the presence of Epstein–Barr virus infection).

Table 98.1 Lymphocyte function as reflected by phases or events of activation

Phases/events of/in activation
Expression of cell surface proteins required to respond to antigenic stimuli (TCR, BCR, CD3, CD19) Calcium influx Expression and/or up- or downregulation of cell surface receptors, important in early activation (CD69, CD25, CD40L) Blastogenesis (mitogenesis) and cell division (measured by a wide range of 'read-out' systems) Up- or downregulation of markers indicating chronic activation, antigen priming (CD71, CD45RO, CCR7, CD62L) Apoptosis (cell death)
Outcome
Production of cytokines in response to polyclonal or antigen-specific stimulation (Th1/Tr1 versus Th2/Tr2) Production of polyclonal or antigen-specific immunoglobulins Specific and non-specific cytolytic activity (see Table 98.3) Measuring suppressive effects (T-regulatory activity, suppression of immunoglobulin secretion)
BCR, B-cell receptor; TCR, T-cell receptor.

the abnormal value(s); does it fit with an immunologic condition? Third, what are the consequences (significance) for the patient? Are immediate interventions indicated, such as intravenous immunoglobulin (IVIG), antibiotics, and patient isolation? When dealing with pediatric patients, a fourth question should be asked: how do the patient's laboratory results compare to age-appropriate normal values/reference ranges?

Controls (i.e., presumed healthy individuals) play important roles in all immunologic assays. Broadly categorized, there are assay controls and interpretation controls. Assay controls are needed to ensure that the assay is performing adequately (including shipping controls if the blood has to travel to the laboratory). In addition to a healthy control, the patient or subject constitutes an internal assay control (i.e., intra-assay control) to distinguish between 'noise' and 'signal' (e.g., cells cultured in the presence (signal) and in the absence (noise) of mitogens). Controls are also needed in the interpretation of the results, providing a framework for comparison. This includes the results of the healthy control, analyzed in parallel with the patient, and results from other control subjects, captured in a reference (normal) range. As mentioned in the introduction, the use of demographics-matched controls (age – both young and old – gender, ethnicity) is important for many assays.

The patient should be the starting point and the endpoint of the immunologic investigation. To guide the appropriate choice of functional assays for immune competence, it is imperative to have an initial assessment of immunologic phenotype (that could follow from function or lack thereof), linked to a specific question that is posed by the patient's clinical scenario. In many or most cases, clues to the nature of the functional defect are provided by abnormal phenotype (examples in Fig. 98.1). It is recommended to develop concepts as to the likely explanation of abnormal phenotype and the associated clinical scenario, anticipating how the data/results of functional assays will fit in these concepts. This approach should, however, be balanced by keeping an open mind, especially if few clues are available, or if clues seem contradictory. *An important aspect of functional testing is in fact obtaining the right assay(s) for the right scenario.* For example, obtaining a proliferation assay to

CLINICAL PEARLS

AVOIDING PITFALLS OF *IN VITRO* ASSAYS

What do we need to know about the patient?

Demographic data (age, sex, ethnicity, smoking)
 Exposure history (natural infections, vaccinations)
 Medications (immunosuppression)
 Relevant (current) medical scenario (viral infection, trauma, cancer)
 Interfering factors *in vivo* (rheumatoid factor, heterophile antibodies)

What do we need to know about the assay?

Cell source and viability (fresh, shipped, cryopreserved)
 Cell manipulation, requirement for other cells (antigen-presenting cells, interfering suppressor T cells)
 Controls (assay controls, including intra-assay, interpretation controls)
 Data scoring (ELISPOT), calculation, and representation (e.g., counts per minute, lytic units)

measure T-cell responses to recall antigens would be of no value if the antigen has not been experienced and thus cannot "recall." Many other such examples can be envisioned.

FUNCTIONAL ASSAYS OF T-CELL IMMUNE COMPETENCE

Functional assays of T cells are generally intended to determine: (1) global immune competence; (2) specific (selective) immune competence; (3) *in vivo* state of immune activation; (4) recovery of *in vivo*

Table 98.2 Methods of lymphocyte activation *in vitro*

Frequency ^a	Stimulator	Target	Remarks
	Phorbol esters PMA	Protein kinase C	Stimulates both T and B cells (similar for ionophores)
~80–90%	Ionophores Ionomycin	Ion channels	PMA + ionomycin: bypasses cell surface receptors and early signaling molecules
~60–70%	Mitogens PHA ConA PWM	Multiple receptors Multiple receptors Multiple receptors	T-cell stimulator (carbohydrate-recognizing lectin) (mitogen stimulation assay) T-cell stimulator (carbohydrate-recognizing lectin) (mitogen stimulation assay) T-cell stimulator and T-cell-dependent B-cell stimulator (mitogen stimulation assay)
~40–50%	Antibodies/ligands Anti-TCR Anti-CD3 Anti-CD28 Anti-IgM Anti-CD40 or sCD40L	TCR–CD3 complex TCR–CD3 complex CD28 on T cells BCR CD40	Mild mitogen in soluble form; potent if immobilized on membranes or beads Not mitogenic unless used in combination with TCR/CD3 stimulation Potent if immobilized; ± T cells or T-cell supernatant to test regulatory T-cell effects Polyclonal immunoglobulin secretion; isotype determined by cytokine addition
~20–30%	Microbial antigens SEB SAC	TCR (noncognate) BCR	Superantigen, stimulates ~20% of T cells through an invariant domain of the TCR SAC + IL-2: polyclonal immunoglobulin secretion in the absence of T cells
~5–10%	Allogeneic cells	TCR + others	One-way, two-way mixed lymphocyte culture (MLC)
< 1%	Recall antigens Tetanus Candida	TCR (cognate) TCR (cognate)	Dependent on prior <i>in vivo</i> exposure to tetanus (vaccination) (antigen proliferation assay) Dependent on prior <i>in vivo</i> exposure to <i>Candida</i> spp. (antigen proliferation assay)
^a Estimates of frequencies of responding T cells. BCR, B-cell receptor; ConA, concanavalin-A; IgM, immunoglobulin M; IL-2, interleukin-2; PHA, phytohemagglutinin; PMA, Phorbol myristate acetate; SAC, <i>Staphylococcus aureus</i> Cowan strain; SEB, Staphylococcal enterotoxin B; TCR, T-cell receptor.			

immune activation following immunosuppression; (5) appropriate downregulation of immune activation, and induction of cell death; (6) determination of prior exposures to foreign antigens (through infection or immunization); and (7) major histocompatibility complex (MHC) transplantation compatibility and evidence of prior exposure to alloantigens.

It should be possible to obtain a fairly detailed assessment of the T-cell compartment with a combination of immunophenotyping (Chapter 97) and functional assays (Table 98.2). This should allow hypotheses, regarding the immunologic nature of the clinical scenario, to be accepted or rejected. Depending on the complexity of the clinical circumstance, immunophenotyping can vary from a screening assess-

ment of basic lymphocyte subsets to an advanced-flow cytometric analysis of subset, activation, effector, adhesion and many other cell surface and intracellular markers (beyond the scope of this chapter). The choice of functional assays is also determined by the complexity of the clinical situation (and pretest determination of form). For patients with immunodeficiency states that are predominantly characterized by issues with host defense (infections), performing a mitogen stimulation assay, employing combinations of phytohemagglutinin (PHA), concanavalin-A (Con-A), and pokeweed mitogen (PWM), immobilized anti-CD3, and/or an antigen stimulation assay are sufficient for the assessment of T-cell immune competence.²⁻⁵

In patients with suspected complex cellular immunodeficiency states, combinations of functional assays that have different cellular requirements and/or divergent pathways and modes of activation may be helpful to develop an understanding of the underlying defect(s), especially if these assays impose an incremental stringency on the T-cell compartment (e.g., the estimated percentage of T cells that can respond to the stimulus). For example, PMA and ionomycin can bypass relevant cell surface receptors, such as the T-cell receptor (TCR)–CD3 complex and upstream signaling components, connected to these receptors, allowing the vast majority of T cells to show a response. On the other end of the spectrum is the response to recall antigens, which typically involves less than 1% of the entire T-cell compartment (see Table 98.2 for a global overview). Adding growth factors (e.g., interleukin-2 (IL-2)) may provide additional information regarding the functional status of the cell population. Two examples of this principle are demonstrated in Figure 98.2, showing differential responses to phorbol esters, ionophores, mitogens, and the effect of exogenous cytokines (IL-2) in 2 patients with relatively similar clinical scenarios, characterized by infections and T-cell immunodeficiency.⁶ Similar studies are helpful in other scenarios (e.g. ZAP70 defects that show abnormal TCR/CD3 stimulation but normal responses to stimuli that bypass the ZAP70 adaptor protein, such as achieved with PMA and ionomycin).⁷

As with most functional assays, the clinical utility of the assays described above depends on the ability of the clinician to translate raw data into an appropriate interpretation of the results. It seems self-evident that completely normal and completely abnormal results are relatively easy to explain; everything in between (the gray zone) is, more or less, a matter of an educated interpretation. Detailed functional analysis, as shown in Figure 98.2, can help in making the gray zone easier to navigate. This of course is balanced by the added technical challenges (and potential pitfalls) of these labor-intensive assays. In the event that the results of the functional assay do not fit with the observed form, an attempt should be made to explain whether this discrepancy has a biological basis or is due to assay-related artifacts (technical issues). Thus, it is crucial that adequate quality control programs are in place to ensure that data interpretation and its consequence on clinical management are valid. Essentially every aspect of functional assays is subject to variation that can influence its performance. An evaluation of T-cell immune competence can be achieved without obtaining a blood sample. Delayed-type hypersensitivity skin testing constitutes an *in vivo* method for determining (screening) cellular immunity based on prior exposure to certain pathogens. Its major advantages are convenience, availability, and quick turnaround time (~48–72 hours). In addition, DTH skin tests measure both the afferent (e.g., antigen presentation) and efferent loops of the immune response (e.g., T-cell infiltration, mediator release). An obvious limitation is that exposures to the agents used in DTH must

have taken place. Clinical relevance and use of DTH tests to detect incompetent T-cell function are limited by the facts that the response cannot be adequately quantified and that there are many causes of false-negative results (anergy). Among the latter are young and advanced age, concurrent infections, use of immunosuppressive medications, malnutrition, atopic dermatitis, and others. Thus, DTH tests ideally include at least a combination of several recall antigens (e.g., tetanus toxoid, *Candida*, mumps) placed by intradermal injection to increase the probability of a positive response (i.e., erythema and induration at 48 and 72 hours after application). This testing should not be performed on children under the age of 1–2 years and negative results should be interpreted with great caution (positive results can be used to plan subsequent *in vitro* studies, if necessary).^{8,9}

ASSESSMENT OF CYTOLYTIC FUNCTION

Assays which measure proliferation to mitogens, antigens, and cytokines reveal the ability of T cells to divide appropriately and produce soluble products in response to stimulation. However, the effector function of cytotoxic lymphocytes requires both proliferation and the ability to kill target cells. Cytolytic function pertains to subsets of T and NK cells. There are several types of cytolytic activity that differ in respect to effector cell population, specificity (e.g., MHC restriction), requirement for prior sensitization to the target, and other features (Table 98.3).¹⁰⁻¹² While both T-cell subsets and NK cells can function as non-MHC-restricted cytolytic cells, only T cells have the ability to kill target cells via cognate (MHC/peptide) recognition, a process that requires prior exposure to the target or antigens derived from the target.^{13,14} Antibody-dependent cellular cytotoxicity (ADCC) is a cytolytic process that is dependent on the cooperative interaction of several different cellular and humoral constituents of the immune system. In ADCC, effector cells with receptors for the Fc portion of antibodies (e.g., CD16) infer target cell lysis by using these Fc receptors to attach to antibody-coated target cells.^{15,16} Lymphokine activated killer (LAK) cells are cytotoxic cells, mostly, but not exclusively, derived from NK cells that, through activation by IL-2, acquire more potent cytolytic function to “traditional” targets, as well as broaden the repertoire of potential targets (e.g., fresh tumor cells).^{17,18}

Cytolytic activity can be divided into three phases that can be assessed *in vitro*. The process starts with conjugate formation between target and effector cells, mediated by many receptor/ligand pairs. Following cellular contact, the cytolytic cells are triggered, i.e., prepared for imminent killing. This process can be measured on the basis of calcium flux or by intracellular phosphorylation events. The process is completed (and can be repeated with other targets) by lysis of target cells through membranolytic/secretory (perforin and granzymes) and by nonsecretory receptor-mediated (Fas/Fas ligand) mechanisms.¹⁹⁻²²

Reasons for obtaining cytolytic assays broadly follow the same considerations as for assays measuring T-cell immune competence. It has long been recognized that abnormal cytolytic function is found in patients with a variety of disorders that include primary and acquired immunodeficiency disorders, viral infections, cancer, trauma/burns, and other conditions, some of which are better characterized than others (e.g., chronic fatigue syndrome).^{12,23} From a practical standpoint, however, it is often difficult to translate the results of these assays into meaningful interpretations that are actually helpful in the diagnosis and management of these conditions. Development of new therapeutic options for some

Assay description: PBMCs are incubated with various stimulators of mitosis. After sufficient time to allow cells to begin proliferating, radioactive thymidine is added to the cultures. The amount of radioactivity taken up by the cells measured and represents cells undergoing DNA synthesis. An abnormal result may indicate an inability of the cells to proliferate.

Test Limitations: This test has not been validated for diagnostic.

Stimulator	Patient results (cpm)	Control of the day (cpm)

diagnosis

Assay description: PBMCs are incubated with various stimulators of mitosis. After sufficient time to allow cells to begin proliferating, radioactive thymidine is added to the cultures. The amount of radioactivity taken up by the cells measured and represents cells undergoing DNA synthesis. An abnormal result may indicate an inability of the cells to proliferate.

Test Limitations: This test has not been validated for diagnostic.

Stimulator	Patient results (cpm)	Control of the day (cpm)
3 day: unstimulated	256	447
PHA (25ug/ml)	3,311	181,634
PMA (500ng/ml)	3,080	76,308
Ionomycin (0.5ug/ml)	303	418
Ionomycin (1.0ug/ml)	432	881
Ionomycin (2.0ug/ml)	548	11,840
25ug/ml PHA + 100ng/ml PMA	11,446	42,964
10ng/ml PMA + 0.5ug/ml Ionomycin	18,661	198,947
5 day: unstimulated	385	1269
PHA alone	1,263	55,665
LCL alone	32,777	192,061
IL 2 alone	43,063	61,213
PHA + IL 2	35,513	54,364
LCL + IL 2	236,766	170,159

3-yr old girl with atypical presentation of T-cell deficiency, corrected with exogenous IL-2 administration

Fig. 98.2 (A and B) T-cell immunocompetence testing. Examples of comprehensive assays for measuring T-cell immune competence.

Table 98.3 Types of cytolytic function

Type of cytotoxicity	Specificity	Cell(s)	Targets	Enhancing factors
Natural killer (NK) cell function	Nonspecific	NK cells (CD16+, CD56+)	K562 cells	Interferon
Antibody-dependent cellular cytotoxicity (ADCC)	Specificity dependent on antibody	NK cells, monocytes, macrophages, granulocytes	Chang cells, Raji cells	Opsonized immunoglobulin G
Cytotoxic T-cell function	Specific, HLA-restricted	T cells	EBV-transformed B-lymphoblastoid cells	Viral/tumor antigens
Cell-mediated lympholysis	Specific, HLA-restricted	T cells	Allogeneic cells	Alloantigens
Lymphokine activated killing (LAK)	Nonspecific	NK cells, T cells, monocytes, macrophages	Daudi cells, patient-specific tumor cells	IL-2 (IL-12, IL-15)
Lectin-dependent cytotoxicity	Nonspecific	NK cells, T cells, monocytes, macrophages	See above (killing induced by lectin interaction)	Mitogens (lectins)

EBV, Epstein-Barr virus; HLA, human leukocyte antigen; IL, interleukin.

these disorders (e.g., immunotherapy of cancer, novel vaccines) has invited a new look at cytolytic assays, particularly with respect to the measurement of antigen-specific cytotoxicity. Determination of cytolytic function has particular value in hemophagocytic lymphohistiocytic (HLH) disorders, including inherited (familial) forms of HLH, as well as secondary forms of HLH (e.g., viral-induced, as part of malignancies and rheumatologic disorders).^{24–26} In these disorders, other measurements of function are often normal or, from an interpretation standpoint, situated in “the gray zone.” Again, it is the integration of the clinical vignette of the patient and detection of abnormal form (see example in Fig. 98.1G) that guides which cytolytic assays are most appropriate (the right assay for the right situation).

In the repertoire of *in vitro* cytolytic assays, the 4-hour ⁵¹Cr-release assay using the NK-cell-sensitive K562 tumor cell line is relatively straightforward from a technical and quality control aspect and has data and results that fit reasonably well into established clinical patterns.²⁷ Measuring cytotoxic T-lymphocyte (CTL) function is useful to complement other studies of T-cell immune competence and to compare with non-MHC-restricted killing (NK-cell function). CTL assays can be done by a variety of methods, including initial priming of effector T cells to irradiated target cells (e.g., Epstein–Barr virus-transformed B cells) in a 6–7-day culture, followed by restimulation with the same, ⁵¹Cr-labeled, target cells. ADCC capacity can be used to evaluate effector mechanisms of therapeutic monoclonal antibodies in therapeutic trials while the LAK assay can measure cytolytic activity against patient-specific tumor cells in the context of patient-specific cancer immunotherapy trials.^{10, 11, 28}

Common features in cytolytic assays include the use of incremental ratios between the number of effector cells and target cells (E:T ratios) that provide information for comparisons between patients and controls and serve quality control purposes (Fig. 98.3). Specific intra-assay controls include incubating target cells without effector cells (spontaneous lysis) and with detergent for maximum lysis as well as including nonrelevant target cells, adding anti-human leukocyte antigen (HLA) antibodies to block MHC-restricted killing, and using nonantibody-coated target cells in ADCC assays.^{22, 28}

In the interpretation of the raw data, it is again important to consider the variety of assay variables and subject variables that can influence the validity of the data/results. It is our experience that storage, shipping, and cryopreservation are particularly relevant in cytolytic function assays, requiring additional attention to quality control. In the interpretation of the results it is important to consider the range of possible explanations. For example, abnormal NK-cell function can be explained by the absence of NK cells (detected by flow cytometric assessment of lymphocyte subsets), by absence of components of the cytolytic machinery (Fig. 98.1G), predominance of regulatory (CD56-bright) NK cells that do not appear to participate in NK-cell cytotoxicity directly, and other mechanisms or perturbations. Alternatively, abnormal function can be part of more global abnormal lymphocyte function, such as seen in both primary and secondary forms of immunodeficiency. Again, discrepancies between anticipated results and posttest results need to be reconciled, potentially repeating the assays, and/or performing the assays under different conditions (e.g., following resolution of viral infections, discontinuation of immunosuppressive medications).

ASSESSMENT OF B-CELL FUNCTION

Evaluation of defects in the B-cell compartment that underlie some of the more common immunodeficiency disorders follows the same pathway of linking clinical observations with patterns of abnormal form. These include decreased levels of immunoglobulins and an abnormal B-cell phenotype (Fig. 98.1C).^{29–31} Although similar *in vitro* assays that measure B-cell proliferation, as well as nonspecific (polyclonal) and antigen-specific immunoglobulin secretion, can be performed using a variety of *in vitro* culture systems, a sufficiently detailed assessment of B-cell function can generally be obtained through *in vivo* testing. Once abnormal B-cell function has been detected *in vivo*, subsequent *in vitro* testing may provide additional information characterizing the defect in B-cell function. This testing may include determination of the integrity of cellular contact and signal transduction pathways, the effects of cytokines and growth factors on B-cell differentiation, and the capacity of T cells to provide help, or suppress immunoglobulin secretion. These assays are generally performed in specialized research laboratories only.

The extensive menu of contemporary vaccines provides a convenient stage to perform B-cell function analysis based on the production of specific antibodies *in vivo*. In young children, a sufficient number of vaccinations have generally been administered to allow a screening assessment of B-cell function *in vivo* using randomly acquired specimens. In older patients and in patients with an incomplete vaccination history, functional studies of the B-cell system typically include pre- and postvaccination measurements of specific antibody levels, following one or more (booster) vaccinations. Functional assessment of antibody production should measure both responses to protein (e.g., tetanus toxoid) and polysaccharide antigens (e.g., *Streptococcus pneumoniae*).²⁹ The now routine use of conjugate vaccines is of great benefit in providing protective immunity against certain organisms; however, from an immunologic perspective it should be realized that these are predominantly IgG₁- (and IgG₃)-mediated responses, while age-dependent maturity towards anti-polysaccharide immunity is characterized by the development of an IgG₂-mediated response. Nonconjugate versions of polysaccharide-specific vaccines are needed to distinguish between immaturity of the immune system and (permanent) disorders of specific antibody responses to polysaccharide antigens, and the clinical relevance of isolated IgG₂

KEY CONCEPTS

B-CELL TESTING

B-cell testing is done primarily by *in vivo* (vaccination) studies

General considerations for vaccination studies:

Protein vaccines (e.g., tetanus toxoid) measure T-cell-dependent responses

Polysaccharide vaccines (e.g., Pneumovax) measure T-cell-independent responses

Recall antigens: antigen has been experienced previously; antibody produced is typically of isotype-switched subclass (e.g., immunoglobulin G (IgG)) when (booster) vaccine is given

Neoantigens: antigen is new to immune system; antibody production is of nonisotype-switched subclass (IgM) following primary (first) vaccination, and of isotype-switched subclass following secondary vaccination

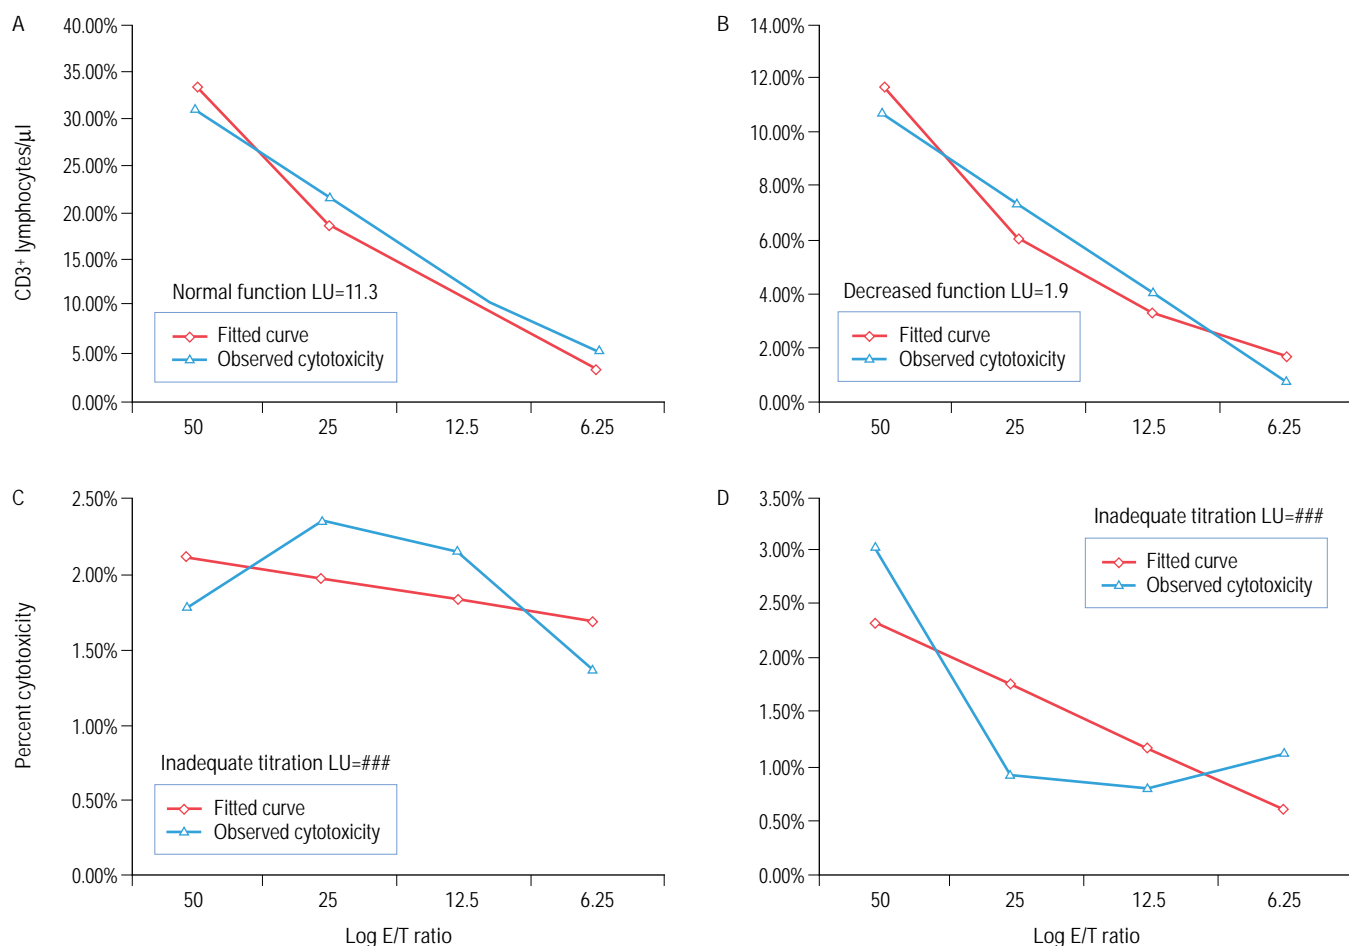

Fig. 98.3 (A–D) Natural killer (NK) cell assays. Examples of NK-cell assay data representation. First, the percentage specific lysis (cytotoxicity) is calculated for each E:T ratio by dividing the average of the experimental ^{51}Cr release (cpm) – the average spontaneous ^{51}Cr release (cpm) by the average of the maximum ^{51}Cr release (cpm) – the average spontaneous ^{51}Cr release (cpm). Next, a graph is constructed with the percentage lysis on the y-axis versus the E:T ratio (50:1, 25:1, 12.5:1, and 6.25:1) on the x-axis. Using the graph, the E:T ratio, which accounts for 10% cytotoxicity (lysis), is plotted in the graph ($E:T_{10}$). To calculate the number of lytic units (LU), the number of target cells used in the assays, which is constant, is used to calculate the E_{10} (set at 1 LU). The final LU is calculated as the number of LU per a predetermined number of effector cells (e.g., 10^6 ; thus 10^6 divided by E_{10} = total LU). The fitted curve represents the actual connected data points, while the observed cytotoxicity is a “best-fit” line mathematically plotted, using lysis at 50:1 and 6.25:1, the standard errors of y-axis estimates and the degrees of freedom). Upper left shows normal NK cell function, while the upper right shows decreased NK-cell function, based on an established normal range (LU=3, being the lower limit of normal in this example). The graphs on the bottom show problems with the generation of fitted curves and their deviation of observed curves, making LU calculations unreliable (although percent lysis for each E:T ratio can still be shown, and, potentially used for interpretation). See also reference 28.

deficiency.²⁹ Nonconjugate vaccines can, in general, be administered in children older than 2–3 years, keeping in mind that immunologic maturity is not reached at the same age by every child.

Antibody levels (titers) are often reported relative to protective values. These values should be regarded with caution as they are based on epidemiologic data regarding protection in large populations. For randomly acquired antibody levels, an initial comparison to protective values can be used to decide if further vaccination studies are warranted. In other scenarios it is recommended to use the patient as his/her own control and

determine a change in antibody levels between pre- and postvaccination. At least a fourfold increase can be considered a normal response to a protein antigen, and a two- to fourfold increase a normal response to a polysaccharide antigen. It is not recommended to administer multiple vaccines concurrently, as this may interfere in the immune responses. Also, it has been observed that hyperimmunization, as well as vaccination following (recent) exposure to the antigen via a natural infection, may lead to a decreased antibody response. A recent naturally acquired infection represents an appropriate alternative to vaccination, but it necessitates that

information is available regarding the responsible organism, possibly including serotype (e.g., *S. pneumoniae* serotype). No live vaccines should be used to evaluate the functional status of the immune system in patients with suspected immunologic disorders.

Evaluation of an antibody response is a critical part of evaluating many immunodeficiency disorders as well as characterizing functional immune reconstitution following bone marrow transplantation, chemotherapy or anti-human immunodeficiency virus (HIV) viral therapy. When abnormal, it may be important to determine whether the abnormal responses *in vivo* are due to a primary B-cell defect, a primary T-cell defect, or a combination of the two. Vaccinations based on recall antigens will not provide a clear, or complete, picture as to the origin(s) of abnormal B-cell function. This information can be obtained if a vaccine contains a neoantigen (i.e., an antigen that has not previously been encountered) that induces an immune response, in which contributions by T cells and B cells are well characterized. For example, the T-cell-dependent neoantigen bacteriophage phi-X174 has been extensively studied in inherited and acquired human immunodeficiency conditions; primary and secondary responses, isotype switching, as well as antigen clearance can be measured after a primary, secondary, and subsequent vaccinations, and compared to a well-established normal range.^{32, 33} Other (potential) neoantigens that have been relatively well characterized are keyhole-limpet hemocyanin (KLH) and rabies vaccine (Food and Drug Administration-approved).^{34, 35} An added benefit of bacteriophage (and KLH) is that vaccination studies can be done while the patient continues to receive IVIG substitution (note: B-cell immunophenotyping can also be performed while patients receive IVIG). Interpretation of data follows the same considerations; clearly normal and abnormal results are relatively easy to explain, while other results require some degree of speculation. *In vitro* studies of B-cell function (examples in Table 98.2), including the removal and addition of T cells (and other cells) and supernatant/serum may provide additional insights into the integrity of the B-cell compartment.

Using a combination of *in vivo* B-cell assessment and a limited number of *in vitro* assays for the T- (and NK-) cell compartments, sufficient data are typically available to explain many alterations in immunologic function, linked to a defined repertoire of clinical scenarios. Detection of abnormal immunologic form should not be an afterthought; rather, it should go hand in hand with functional assays. In fact, the continued development and refinement of flow cytometry-based “read-out” systems linked to cell function create opportunities to dissect cell characteristics and functional properties simultaneously.

RESEARCH IMMUNOLOGY

As mentioned, the separation between clinical and research immunology testing is largely arbitrary. In this section, attention is paid to novel methodology and applications, designed and refined in response to new basic and clinical science discoveries and/or clinical needs.

MEASURING AND CHARACTERIZING ANTIGEN-SPECIFIC T CELLS

Enumeration and characterization of antigen-specific lymphocytes and their effector functions are popular topics in laboratory immunology, as judged by a rather dramatic increase in available methodology. Using stimulation designed to measure the response of only antigen-specific

lymphocytes, intracellular events such as activation of signal transduction proteins and extracellular responses such as cytokine secretion may be determined. These measurements are based on flow cytometry, enzyme-linked immunosorbent assay (ELISA), and enzyme-linked immunosorbent spot (ELISPOT) technology. The evolution of these techniques has to a large degree been driven by a requirement for accurate, sensitive, specific, and reproducible data regarding antigen-specific T cells in scenarios of HIV and other infections (e.g., vaccines), cancer (e.g., anti-tumor vaccines) and autoimmune disease. In addition to direct *ex vivo* visualization and enumeration of these cells, functional correlates (*ex vivo*, *in vitro*) are needed to assess the overall efficacy of current and future therapies in these and other settings.

Traditionally, enumeration of antigen-specific T cells has been achieved by limiting dilution analysis (LDA). This technically difficult assay provides an estimate of the precursor frequency of a particular T-cell population, and can be used to measure specific cytotoxicity of the cells (CTL). Alternatively, LDA-cultured cells can be assayed with respect to cytokine secretion in the supernatant (helper T cells). These studies require large volumes of blood and arbitrary distinction between positive and negative culture wells. In addition, differentiation, cellular proliferation, and survival during the culture period (e.g., 9–14 days) are necessary, often leading to underestimation of the number of antigen-specific T cells.

The problem of underestimating cell frequency in LDA assays has been validated by several innovative new methods of antigen-specific T-cell analysis. MHC/peptide tetramer, or more broadly designated, MHC/peptide complex technology, allows for direct visualization, enumeration, and characterization of antigen-specific T cells *in vivo*.^{36, 37} The main limitation of this technology is the need to know HLA restriction of the peptide together with information on the HLA type of the patient (some of whom will not be evaluable due to HLA incompatibility with the tetramer). No prior knowledge regarding peptide configuration and its HLA specificity is needed for two other methods of enumeration of antigen-specific T cells: measurement of intracellular cytokines in T-cell subsets by flow cytometry (IC-FCM) and measurement of secreted cytokines by ELISPOT technology (see Fig. 98.4 for schematic of ELISPOT).^{38, 39} In both methods, T cells are cultured and activated (for several hours to days) *in vitro* with the antigen of interest (e.g., HIV or other viral antigen, tumor antigen). An additional advantage to these techniques is that T cells can be recovered for subsequent studies (e.g., gene profiling). In the IC-FCM assay, cytokines of interest are visualized inside cells while simultaneously characterizing the cell surface antigens of the responding cells. Variation of culture time can be used to select for existing (*in vivo*) memory cells by limiting the culture period to several hours, or to select naive T cells by culturing for days.

ELISPOT is a variant of standard ELISA technology.⁴⁰ Cytokines produced by cultured antigen-specific T cells are allowed to be secreted and bind to primary antibodies that have been immobilized in ELISPOT wells. Secondary antibodies conjugated to color-producing enzymes bind to the “captured” cytokines and addition of the substrate identifies each cell producing the cytokine(s) of interest. As shown in Table 98.4, ELISPOT technology seems the most sensitive technique to detect antigen-specific T cells, especially if interferon- γ (IFN- γ) and tumor necrosis factor- α (TNF- α) are measured.^{38, 39}

The main impetus to develop, refine, and apply these technologies comes from new therapeutic approaches that are highly disease-specific

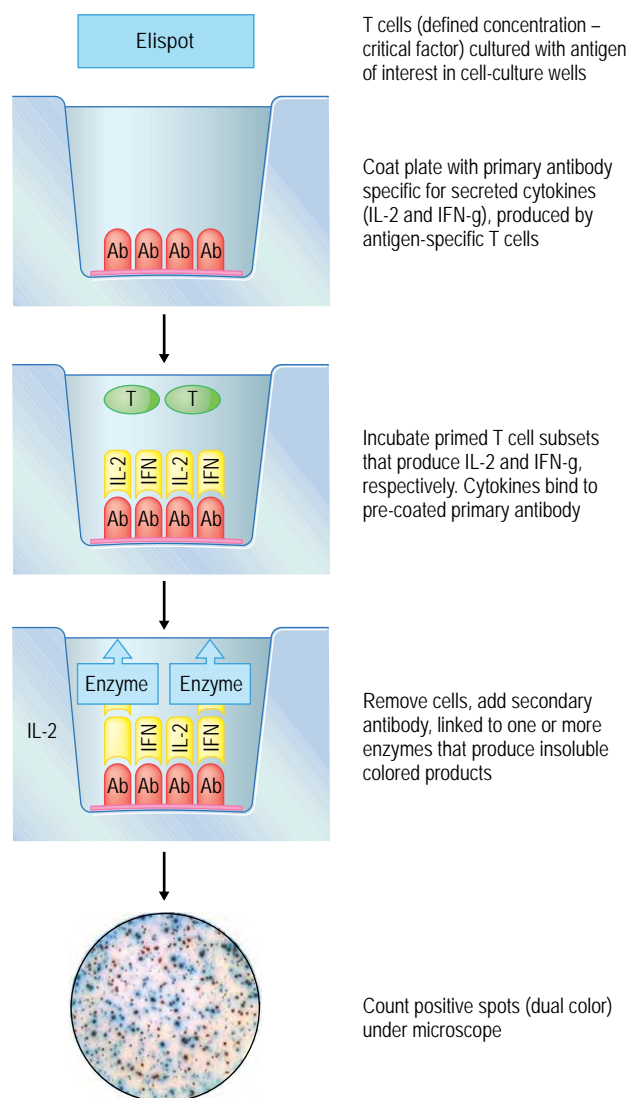

Fig. 98.4 Principle of ELISPOT assay. The principle of ELISPOT can be used to enumerate antigen-specific T cells *in vivo*, for example in response to infection or vaccination. A predetermined number of T cells are cultured *in vitro* for a number of hours to days (depending on the type of responding cells of interest). Antigen specificity is determined by production of effector cytokines (e.g., interleukin-2 (IL-2), interferon- γ (IFN- γ)) in cytotoxic T cells, responding to tumor. A combination of different secondary antibody–enzyme complexes are used to develop two-color ELISPOT.

and are not suitable for evaluation in animal models. Thus, robust, reproducible, and rapid generation and analysis of large data sets are needed to evaluate efficiently new immunotherapeutic modalities. The assays described above appear to fill this need and provide useful information, necessary for optimizing novel treatments of cancer, infections, and autoimmune disease.

EMERGING IMMUNE DISORDERS

The need to develop new sensitive and specific tools to study immune function is illustrated by the recognition of ‘emerging’ immunodeficiency disorders that are not easily diagnosed by standard approaches (overview in Table 98.5). For example, it has become apparent that defects in nuclear factor κ B (NF- κ B) activation and processing result in immunodeficiency, with and without ectodermal dysplasia (ED). Several new gene defects, related to abnormal activation of NF- κ B, have been identified in individuals presenting with recurrent infections.^{41, 42} In most cases, T-cell function, as measured by standard techniques, is intact and generally nonrevealing. The only functional abnormality consistently observed in boys with immune deficiency and ED associated with defects in the NF- κ B essential modulator (NEMO) is poor response to polysaccharide vaccines. The second gene, associated with defective NF- κ B activation and immune deficiency, encodes an inhibitor of NF- κ B (I κ B α). This inhibitor is normally involved in retaining the NF- κ B protein in the cytoplasm. In one reported patient, the clinical phenotype was similar to defects in NEMO, showing ED and recurrent bacterial infections. However, the patient displayed significantly depressed proliferative T-cell responses to recall antigens. The third gene defect, interleukin-1 receptor-associated kinase (IRAK-4), has been identified in patients with a history of recurrent pyogenic infections, but normal serologic response to vaccinations.⁴³ This disorder is associated with an abnormal response to the Toll-like receptor (TLR) pathway ligand, lipopolysaccharide (LPS), linked to defective IL-1 receptor (IL-1R) signaling.

Currently, there is no standard approach to diagnose any of these mentioned disorders; the diagnosis requires genetic sequencing in the context of an appropriate clinical scenario and in the absence of readily identifiable alternative defects. So far, there is evidence to suggest that patients with NEMO and I κ B α deficiency may have abnormal signaling through TLR, IL-1R, and TNF receptor (TNFR) family members such as CD40, TNFR, and the ED receptor itself.^{41, 42} In contrast, IRAK-4 deficiency leads to abnormal signaling through TLR and IL-1R, but not TNFR, family members.⁴³ Therefore, a clinically useful immunologic assay to characterize these defects would be to measure the NF- κ B response through stimulation of all three types of receptors (TLR, IL-1R, and TNFR). One approach along these lines is to collect peripheral blood mononuclear cells (PBMC) from patients and controls, place cells in culture with TNF- α , IL-1 β , and LPS, and subsequently measure cytokine secretion (IL-6, TNF- α , IL-1 β) by IC-FCM, ELISA, or ELISPOT. An additional method of measuring NF- κ B activation is based on flow cytometric detection of phosphorylated, active, NF- κ B proteins in the cytoplasm prior to translocation to the nucleus, or to measure the binding of activated NF- κ B proteins to plate bound oligonucleotides, specific for the NF- κ B activation site. Reagents for these procedures are commercially available, and the technical aspects are all relatively worked out. There are now commercially available flow cytometric assays focused on evaluating the phosphorylation of intracellular messenger proteins.

In addition to recurrent bacterial infections, patients with defects in NEMO are also at risk of developing mycobacterial infections. This is likely due to abnormal monocyte function. Monocytes in patients with NEMO defects exhibit decreased IL-12 production in response to NF- κ B activation pathway through CD40L stimulation.⁴¹ IL-12 production by monocytes is required to induce IFN- γ production through NF- κ B activation, creating a feedback and amplification loop of immune

Table 98.4 Enumeration of antigen-specific T cells

Assay	Sensitivity (cells)	CTL type		
		Effector	Precursor	Memory
⁵¹ Cr release – without <i>in vitro</i> restimulation	1 in 1000	+	+	+
⁵¹ Cr release – with <i>in vitro</i> restimulation	1 in 50 000	+	–	±
Limiting dilution assay (LDA)	1 in 1000 to 1 in 50 000	–	+	–
Tetramer (and variants) analysis (flow cytometry)	1 in 10 000	+	+	+
ELISPOT	1 in 100 000	+	–	+
Intracellular cytokine detection (flow cytometry)	1 in 1000	+	+	+

Table 98.5 Emerging primary defects in host defense

Gene defect	Affected pathway	Functional assessment
NEMO	NF-κB activation	IL-1R, TNFR family, or TLR family stimulation of cytokine production
IκBα	NF-κB activation	IL-1R, TNFR family, or TLR family stimulation of cytokine production
IRAK-4	NF-κB activation	IL-1R and TLR family stimulation of cytokine production
IL-12 p40	Production of IL-12	Measure IL-12 production in response to IFN-γ and LPS
IL-12Rβ1	Production of IFN-γ	Measure STAT-4 phosphorylation in activated lymphocytes in response to IL-12
IFN-γR1	Response to IFN-γ	Cell surface expression of IFN-γR; cytokine production and abnormal STAT-1 phosphorylation
IFN-γR2	Response to IFN-γ	Cytokine production and abnormal STAT-1 phosphorylation
STAT-1	Response to IFN-γ	Cytokine production and abnormal STAT-1 phosphorylation

IFN, interferon; IL, interleukin; LPS, lipopolysaccharide; STAT-1, signal transducer and activator of transcription-1; TLR, Toll-like receptor.

activation. The importance of this cooperative loop between monocytes and lymphocytes is underscored by single-gene disorders of defective production of and/or responsiveness to IL-12 and IFN-γ. Patients suffer from (nontuberculous) mycobacterial infections, as well as infections due to other organisms (e.g., *Salmonella* spp., herpes simplex virus-1, human herpes virus-8).^{44, 45} The abnormal functional characteristics of these disorders are not identified by routine laboratory evaluation, and require specialized (flow cytometry and ELISA-based) assays. For example, defects in response to IFN-γ stimulation due to a problem with IFN-γ receptor (IFN-γR) signaling can be tested by looking at form (i.e., flow cytometric detection of intact cell surface IFN-γR expression), and function by stimulating PBMC with IFN-γ and LPS. Response to stimulation can be measured by phosphorylation of a nuclear signaling molecule, signal transducer and activator of transcription-1 (STAT-1), which also

allows screening for defects in the STAT-1 gene, and by measuring the amount of secreted TNF-α and IL-12 in the supernatant (e.g., ELISA). The responsiveness of activated lymphocytes to IL-12 can be measured by detection of phosphorylated STAT-4. As with NEMO, IκBα, and IRAK-4, these types of functional tests are best conducted in close consultation with experts at tertiary research institutions, who can also assist in identification of gene defects that underlie these disorders.

Defects in immune regulation and homeostasis are receiving more attention as clinical immunologists are becoming increasingly cognizant that the immune response against self as well as against foreign pathogens needs to be regulated and terminated. Our current menu of clinical testing focuses predominantly on diagnosing individuals with clinical pictures of recurrent infections, linked to abnormal T-, NK-, and/or B-cell form and function. At the other end of the clinical spectrum is an emerging field

focused on studying patients with dysregulated lymphoproliferation, autoimmunity, allergy, or malignancy. Here again, the diagnosis is not readily discovered in the clinical immunology laboratory.

In Figure 98.1D, an example is shown with normal function, as measured by standard clinical assays of T-, NK- (and B-) cell function. Nonetheless, the presence of abnormal T cells, that lack expression of CD4 and CD8 and express TCR- α/β (double-negative T cells), is a direct consequence of defective function, namely abnormal Fas-mediated apoptosis (cell death). Apoptosis assays are becoming relevant in the comprehensive evaluation of the immune system as our appreciation for the importance of downregulation and termination of immunologic function has evolved.⁴⁶ Determination of apoptosis *in vitro* is part of the evaluation of autoimmune lymphoproliferative syndrome (ALPS), linking a defined clinical scenario and abnormal immunologic function due to a fundamental defect in Fas-mediated cellular suicide (apoptosis).⁴⁷ Again, an important consideration in the design and execution of apoptosis assays is the right assay for the right setting. For ALPS, the *in vitro* assay must approximate the *in vivo* relevance of Fas-mediated apoptosis. Resting (circulating) T cells are typically not sensitive to undergo Fas-mediated apoptosis *in vivo*. Thus, PBMC (or isolated T cells) are placed in a primary culture system, similar to mitogen or antigen proliferation assays (for example, 2–3 days with PHA, followed by several days of additional culture with exogenous IL-2). This induces the T cells to become sensitive to Fas-mediated apoptosis. At this stage, cells are incubated with anti-Fas antibodies for a 24–48-hour period, after which apoptosis of T cells is measured, using any of a multitude of flow cytometric read-out systems. As has been the theme of this chapter, intrassay (the patient/subject) and interassay (healthy subject) controls should be included. In addition, it is recommended to test non-Fas-mediated apoptosis pathways, for example using chemotherapeutic drugs (staurosporine) and gamma irradiation, to determine specificity of the apoptotic defect. Further development and refinement of apoptosis assays appear to indicate the existence of other defects in specific modes and pathways of apoptosis, some with their own clinical scenarios and observed altered form.⁴⁶

Expression of CD25 on (CD4+) T cells (Fig. 98.1B) does not only, or always, reflect a state of T-cell activation. Within this population, recent advances in basis science have identified unique T cells, often designated CD25^{bright} (see box in Fig. 98.1B), that function as regulatory T cells (i.e., T-regulatory cells (Tregs); Chapter 16). Further characterization has shown these cells to be positive for intracellular expression of cytotoxic T-lymphocyte-associated protein 4 (CTLA4) and forkhead box P3 (FOXP3). Tregs are found in peripheral blood, thymus, lymph nodes, and a variety of other tissues, including gut and endocrine organs.⁴⁸ The importance of Tregs is illustrated by a primary immunodeficiency disorder, designated as immune dysregulation, polyendocrinopathy, enteropathy, X-linked syndrome (IPEX) (Chapter 35). This disorder occurs in boys who are deficient in the X-linked gene encoding FOXP3.⁴⁹ Patients present with diarrhea or failure to thrive, rash, insulin-dependent diabetes, and other autoimmune endocrinopathies, as well as immune-mediated cytopenias. The underlying genetic defect in IPEX is a direct result of defective generation and function of these regulatory cells. Their unique function is to suppress the proliferation of activated (other) T cells, thereby limiting the immune response to self antigens, and perhaps nonself antigens as well. Functional assays for Tregs have been established in research laboratories. They are based on isolating CD4/CD25^{bright} T cells from PBMC and incubating them in a pre-established concentration with the nonisolated, remaining

(CD25⁻), T cells, antigen-presenting cells, and other cells. Standard proliferation assays are set up using mitogens, anti-CD3, or specific antigens (Table 98.2). In the presence of Tregs, proliferation, as measured by [³H]-thymidine incorporation in dividing T cells, is reduced, while in the absence of these cells, normal proliferation is detected.

Although IPEX is a rare disorder, Tregs have fast become a popular cell population because of their impact on immune-mediated disorders and, consequently, their potential application in counteracting these disorders. It can be envisioned that clinical scenarios, resulting from abnormal regulatory T-cell function (Tregs and other cell populations) will become part of contemporary clinical immunology, following the same principle that abnormal immunologic form reflects abnormal immunologic function.^{48,49}

Together these groups of disorders, including defects in host defense and in immune regulation, will provide ample opportunity for the development and refinement of novel assays of immunologic function. In addition, as has been the case for many other functional assays that seem to have been part of the clinical laboratory since inception, new discoveries will be made that will increase our understanding of the human immune system and how it functions.

Assessment of neutrophil function

Douglas B. Kuhns

99

Neutrophils, also known as polymorphonuclear neutrophils (because of their multilobed nucleus) or granulocytes (because of the numerous granules found in the cytoplasm) are major contributors to the host defense against invading microorganisms, particularly bacteria and fungi. Neutrophils are bone marrow-derived, terminally differentiated cells incapable of further cellular division. They have a short lifespan in the circulation ($t_{1/2}$ = 6–8 hours), but survive an additional 1–2 days in the surrounding tissue.¹ Despite this short half-life, neutrophils in the peripheral blood are normally maintained at 3000–6000 cells/mm³ and represent 30–50% of the circulating leukocytes. There are four pools of neutrophils *in vivo*: (1) the bone marrow pool (~90% of the total); (2) the circulating pool (~3% of the total); (3) the marginated pool adherent to the endothelium (~4% of the total); and (4) the remainder, located in the tissues as exudative or extravasated neutrophils.² About 55–60% of the bone marrow is dedicated to the production of neutrophils.³

Neutrophils, with a diameter of 10–15 μ m and a volume of 346 μ m³, have a unique morphology. The nucleus of the mature neutrophil is segmented into three to five lobes with the chromosomes randomly distributed among the lobes. The cytoplasm represents 63% of the cell, the nucleus, 21%, the granules, 15%, and the mitochondria less than 1%.⁴ The large cytoplasmic granules are heterogeneous in size and shape and contain numerous proteins synthesized during specific maturation stages of neutrophil development. With relatively few mitochondria, neutrophils derive much of their energy from glycolysis, using ample glycogen stores.

In the peripheral blood, neutrophils roll along the vascular endothelium, transiently attaching to, and detaching from, the endothelium. This low-affinity adhesion is mediated by lectin-binding glycoproteins, known as selectins,⁵ expressed on the surface of neutrophils (L-selectin) and vascular endothelial cells (E-selectin). As the rolling neutrophils near the focus of infection, they respond to chemoattractants, e.g., C5a, interleukin-8 (IL-8), platelet-activating factor, leukotrienes, and bacterial formylated peptides generated at the infectious focus resulting in functional activation of the β_2 integrins.⁶ The β_2 integrins are heterodimeric glycoproteins with differing α subunits (CD11a or LFA-1, CD11b or MAC-1, and CD11c or gp150) and a common β_2 subunit (CD18). These adherence receptors recognize extracellular matrix proteins and complement factors

(CD11b/CD18 = complement receptor type 3 and CD11c/CD18 = complement receptor type 4). Activation of the integrins induces tighter adherence of neutrophils to vascular endothelial cells and a cessation of rolling. In addition, the neutrophils undergo a dramatic shape change from the normal spheroid shape with relatively smooth membrane to a flattened triangular shape with ruffled lamellipodia.⁷ Homophilic interactions of platelet/endothelial cell adhesion molecule (PECAM or CD31), a member of the immunoglobulin superfamily that is expressed on the surface of neutrophils and is also localized to the lateral cell–cell junction of endothelial cells, direct the neutrophil to the cell junction.⁸ Neutrophils then detach from the endothelium, and migrate through a gap in the vascular endothelium created by contraction of juxtaposed vascular endothelial cells. Once the neutrophil has migrated from the lumen of the vasculature into the extravascular space, it migrates along chemotactic gradients to the focus of the infection.

In the tissue, neutrophils proceed with their primary function, the ingestion and killing of microorganisms. Neutrophils do not express specific receptors for each specific microorganism. Instead, microorganisms become coated with specific immunoglobulins and complement fragments such as C3b and iC3b. Neutrophils recognize these targets using Fc receptors and adhesion molecules, including the β_2 integrins, particularly CD11b/CD18. Treatment of neutrophils with the chemotactic peptide, formyl-methionyl-leucyl-phenylalanine (fMLF), bacterial lipopolysaccharide (LPS), or cytokines (IL-1, granulocyte-macrophage colony-stimulating factor (GM-CSF), etc.) results in increased expression of neutrophil surface receptors (Fc, CD11b/CD18, and CD11c/CD18). These receptors act alone or synergistically to enhance adhesion of neutrophils to antibody- and complement-coated microorganisms, resulting in increased phagocytosis, respiratory burst activity, and degranulation. Zippering of the receptor–ligand interactions promotes the extension of pseudopods around the organism. As the extending pseudopods meet, the membranes fuse, enveloping the microorganism and resulting in formation of the phagosome.⁹ Defects in any quantitative and qualitative aspects of ligand–receptor interaction may impair phagocytic efficiency.

The neutrophil has an extensive array of storage granules that are defined by the biosynthesis of different granule proteins at different

maturation stages of neutrophil development.¹⁰ Granules are classified into four distinct populations: azurophilic, specific, gelatinase, and secretory granules. Azurophilic granules contain myeloperoxidase, lysozyme, antimicrobial peptides, defensins, proteases, and the lysosomal acid hydrolases. The specific granules contain lactoferrin, lysozyme, and vitamin B₁₂-binding protein, and also serve as storage pools for CD11b/CD18 and cytochrome b₅₅₈ of the O₂⁻ generating enzyme, NADPH oxidase. The gelatinase granules are a subset of the specific granules that have a high content of gelatinase. The secretory granules are highly mobilizable intracellular vesicles that contain alkaline phosphatase and other surface antigens.

As the phagosome forms, the azurophilic granules fuse with the phagosomal membrane, forming the phagolysosome and releasing their complement of acid hydrolases, defensins, and myeloperoxidase. These enzymes can potentiate the digestive and microbicidal activities of the neutrophil. The secretion of specific and secretory granules is thought to release mediators of inflammation (such as lactoferrin) and mediate the translocation of additional receptors (CD11b/CD18, fMLF receptor, and laminin receptors, as well as cytochrome b₅₅₈ of the NADPH oxidase) to the plasma membrane. Translocation of these receptors modulates neutrophil adhesion, movement, phagocytosis, and respiratory burst activity. Factors that can affect signal transduction, metabolic activity, microfilament rearrangement, and microtubule assembly can regulate the degranulation process.

Accompanying the fusion of the granule to the phagolysosome is the assembly of the multicomponent O₂⁻-generating enzyme, NADPH oxidase or phagocyte oxidase (*phox*), an enzyme complex consisting of at least two cytosolic components,¹¹ p47*phox* and p67*phox*, and two membrane components, p22*phox* and gp91*phox*, that constitute cytochrome b₅₅₈.^{12, 13} This enzyme reduces molecular O₂ to O₂⁻ using NADPH generated by the oxidation of glucose through the pentose phosphate pathway. O₂⁻ either spontaneously or enzymatically converts to H₂O₂. In the presence of a metal such as Fe²⁺, H₂O₂ and O₂⁻ can react to form the highly reactive hydroxyl radical, OH•. Alternatively, the azurophilic granule constituent, myeloperoxidase, catalyzes the formation of hypochlorous acid from H₂O₂ and Cl⁻. The combined activities of reactive O₂ species, antimicrobial peptides, and lysosomal hydrolases result in the ultimate destruction of the microorganism. Excess production of reactive O₂ species and release of lysosomal hydrolases into the extracellular milieu can lead to tissue damage and inflammation.

KEY CONCEPTS

>> The stepwise reduction of O₂ leads to reactive oxygen intermediates and finally to H₂O

Neutrophils display a diverse array of cellular functions. Abnormalities in these functions can severely compromise host defense, leading to recurrent bacterial and fungal infections. To localize specific deficiencies of neutrophil function, assays have been developed that mimic these functions both *in vivo* and *in vitro*. Often, a preliminary screening of several neutrophil functions is performed to localize deficits and then more vigorous testing of specific function is performed. Assays to assess neutrophil function should address several limitations – the number of cells required for the assay, the type of cell preparation needed (isolated neutrophils versus whole blood), the overall incubation time for the assay, the complexity of the assay, and the rapidity of data collection. These issues become more critical if multiple functional assays are planned concurrently. Since neutrophils cannot be stored or frozen and maintain viability, control neutrophils from a normal volunteer are generally assayed in parallel to validate the results. Generally, this doubles the number of assays to be performed. Additionally, isolation of neutrophils can take 1–2 hours, limiting the time available for functional assays. Fluorescent probes have increased the sensitivity of many of the assays and eliminated the need for radioactive probes. The use of multi-well plates and multi-well microplate readers has reduced the number of cells required and has facilitated the collection of data.

ISOLATION OF NEUTROPHILS

CLINICAL INDICATIONS AND IMPLICATIONS

Assays that avoid neutrophil isolation are preferred because of the artifactual priming of neutrophils during isolation.¹⁴ However, most assays require isolated neutrophils to eliminate any possible contributions of other leukocytes and blood components. In general, blood should be drawn using either citrate or heparin (10 units/ml) as anti-coagulant and maintained at 20–25°C in polypropylene containers. Most isolation protocols require 1–2 hours to obtain purified neutrophils.

PRINCIPLE AND INTERPRETATION OF LABORATORY ASSESSMENT

Most neutrophil isolation protocols use differences in the cell density as the basis for the separation. The relative densities of blood cells are as follows: erythrocytes > neutrophils and eosinophils > monocytes, lymphocytes, and basophils > platelets. Ficoll-Hypaque is a solution of sodium diatrizoate (a dense, iodine-containing molecule) and Ficoll (a polysaccharide) with a density (1.083 g/cc) that falls between that of neutrophils and that of the mononuclear cells. To isolate neutrophils,¹⁵ whole blood is diluted with saline and underlayered with Ficoll-Hypaque. After centrifugation for 30 minutes at 500 g, the less dense monocytes,

KEY CONCEPTS

>> Because of: (1) the short lifespan of neutrophils and (2) the time required to isolate neutrophils, assays of neutrophil function should have minimal complexity and rapid data collection

lymphocytes, basophils, and platelets remain at the upper interface of the Ficoll-Hypaque while the denser erythrocytes and neutrophils pass through the Ficoll-Hypaque and pellet at the bottom. The mononuclear cells are carefully harvested and the remaining Ficoll-Hypaque aspirated. The erythrocyte/neutrophil pellet is resuspended with saline and mixed with 3% dextran. Dextran promotes the formation of rouleaux by the erythrocytes, causing them to sediment rapidly at 1 g. The neutrophil-enriched supernatant fluid is harvested from the bulk of the erythrocytes. Contaminating erythrocytes are removed by a brief (30-second) hypotonic lysis with 0.2% saline. The isotonicity is quickly restored with an equal volume of 1.6% saline. A second hypotonic lysis removes many of the red cell ghosts. In general, $1-2 \times 10^6$ neutrophils can be isolated per milliliter of whole blood from a normal subject with a normal white blood cell count. A second neutrophil isolation protocol that uses a discontinuous gradient of plasma/Percoll has often been used to minimize exposure of neutrophils to trace contamination by bacterial LPS and reduce neutrophil priming.¹⁶

In our laboratory, isolated neutrophils are routinely frozen in aliquots of 5×10^6 cells/vial. For Western blot studies, neutrophils (1×10^6 cells/ml of buffer) are pretreated for 20 minutes with the cell permeant, irreversible serine protease inhibitor, diisopropylfluorophosphate (DFP, 5mM). The cells are then centrifuged and the supernatant fluid removed prior to freezing. In addition, these frozen neutrophils, though not viable, provide an excellent source of material for isolation of DNA for subsequent genetic analysis.

■ NEUTROPHIL ADHERENCE ■

CLINICAL INDICATIONS AND IMPLICATIONS

Adherence of neutrophils to the endothelium is a prerequisite step to the migration of neutrophils into the tissues. Neutrophils isolated from patients with leukocyte adhesion deficiency type 1 (LAD-1) who lack the common β_2 integrin subunit CD18 exhibit abnormal adherence to endothelium,¹⁷ and therefore are not able to migrate efficiently into the surrounding tissues, often resulting in marked granulocytosis¹⁸ (Chapter 21). LAD-2 is a milder form of the disease in which patients exhibit a defect in fucose metabolism and glycoprotein biosynthesis.¹⁹ Neutrophils from patients with LAD-2 exhibit abnormal expression of the glycoprotein, L-selectin, and fail to roll along the endothelium. However, they do exhibit normal β_2 -integrin mediated adherence.

PRINCIPLE AND INTERPRETATION OF LABORATORY ASSESSMENT

The adhesive function of phagocytes is commonly assessed by passage of 1 ml of whole blood through a column filled with nylon wool. Adherence is measured as the difference in the absolute neutrophil count of the

pre-column sample and of the sample after passage through the nylon wool column.

Alternatively, isolated neutrophils can be induced to bind to plastic using a 96-well plate either uncoated, or coated with fetal bovine serum or a specific extracellular matrix protein such as fibrinogen or fibronectin. Endothelial cell monolayers harvested from human umbilical veins may serve as a more physiological substrate for the measurement of cell adhesion. Isolated neutrophils are pre-loaded with the cell permeant, acetoxymethyl ester derivative of the fluorescent dye, calcein (calcein-AM). Nonspecific esterases in the cytosol cleave the ester linkage, trapping the fluorescent probe in the cytosol. The labeled neutrophils are added to each well and incubated in the absence or presence of phorbol myristate acetate (PMA) to promote adherence through activation of the integrins. At the end of the incubation, the wells are washed three times to remove nonadherent cells. The fluorescence of each well is determined with a fluorescent microplate reader and compared to the fluorescence of a control well with a fixed number of fluorescent cells. As shown in the left panel of [Figure 99.1](#), under control conditions, fewer than 10% of the neutrophils adhere to plastic or to plastic coated with fetal bovine serum. Slightly more neutrophil adherence is observed on wells coated with fibrinogen. Treatment of normal neutrophils with PMA for 30 minutes results in the adherence of >90% of the neutrophils under all conditions. This adherence assay is valuable in the diagnosis of patients with leukocyte adhesion deficiency. As shown in the right panel of [Figure 99.1](#), neutrophils isolated from patients with LAD-1 generally exhibit <5% adherence under control conditions and do not increase adherence after treatment with PMA.

■ NEUTROPHIL CHEMOTAXIS ■

CLINICAL INDICATIONS AND IMPLICATIONS

Neutrophil migration is a prerequisite for neutrophil accumulation at sites of inflammation. Patients with leukocyte chemotactic defects usually show recurrent skin abscesses and occasional life-threatening invasive infections.

PRINCIPLE AND INTERPRETATION OF LABORATORY ASSESSMENT

Assessment of neutrophil chemotaxis *in vivo* can be evaluated using skin windows. Skin blisters are gently raised on the volar surface of the forearm using a vacuum pump and an 8-well blister device, with little hemorrhage and vascular damage. The roof of the blister is removed and the exposed skin lesion is bathed with autologous serum using a skin window chamber. In 24 hours, exudative neutrophils accumulate in the autologous serum bathing the skin lesion. The skin chamber provides a mechanism for characterizing the immune cells, as well as soluble immune mediators, that accumulate in the autologous serum during the evolution of the inflammatory response.²⁰

Chemotaxis *in vitro* is generally measured using a Boyden chamber. The Boyden chamber includes three components: a lower (chemoattractant) chamber, a nitrocellulose or polycarbonate filter layer, and an upper cell chamber. The lower compartments of the Boyden chamber are filled with a chemoattractant such as fMLF (10^{-8} M) or IL-8 (10 ng/ml). Recently, a rapid fluorescence-based measurement of neutrophil chemotaxis has been

■ KEY CONCEPTS

- >> In general, $1-2 \times 10^6$ neutrophils can be isolated per milliliter of whole blood from a normal subject with a normal white blood cell count

Fig. 99.1 Adherence of neutrophils to plastic: normal versus leukocyte adhesion deficiency. Neutrophils (1×10^7 cells/ml HBSS without divalent cations) were preloaded with acetoxymethyl ester derivative of calcein (calcein-AM: $5 \mu\text{g/ml}$) for 15 minutes at 37°C . The cells were washed twice and resuspended in Hanks' balanced salt solution (HBSS)/4-(2-hydroxyethyl)-1-piperazineethanesulfonic acid (HEPES) with 2% bovine serum albumin (BSA) at a cell concentration of $2 \times 10^6/\text{ml}$. The wells of a 96-well plate were coated for 1 hour at 37°C with $32 \mu\text{l}$ of either buffer alone, fetal bovine serum, or fibrinogen (2.5 mg/ml). The wells were washed three times and then cells were added to each well ($160 \mu\text{l/well}$, $3.2 \times 10^5/\text{well}$). After a 10-minute preincubation at 37°C , PMA (100 ng/ml) was added and the plate was incubated for 30 minutes at 37°C . The wells were then washed three times with HBSS/HEPES to remove nonadherent neutrophils. The percentage of adherent cells was determined by the ratio of the fluorescence of the well compared to the fluorescence of a known standard well. The panel (NL) on the left represents the data (mean \pm sd) from 22 normal subjects and the panel on the right represents the data from 3 patients with leukocyte adhesion deficiency.

developed that uses a new 96-well disposable chemotaxis chamber²¹ that can be read in a fluorescence microplate reader. The lower chamber contains the chemoattractant and is separated from the cellular compartment by a filter. However, instead of a top chamber, the filter has a hydrophobic mask around each filter site that creates surface tension in the cell suspension, and aligns the suspension on the hydrophilic filter located directly above the chemoattractant chamber. Calcein-labeled neutrophils are placed on top of the filter. The chemotaxis chamber is incubated for up to 60 minutes at 37°C . Nonmigrating neutrophils atop the filter are rinsed off with buffer and then the plate is read in a fluorescence microplate reader. The number of migrating neutrophils can be determined by comparison of the fluorescence to a standard well with a known number of fluorescent neutrophils. Fewer than 5×10^6 fluorescent neutrophils are needed to determine neutrophil chemotaxis using several doses of the chemoattractants, fMLF, IL-8, C5a, and leukotriene B₄. The advantages of this assay are high sensitivity, rapid acquisition and analysis of data, and reduced labor in loading the cell suspension and acquiring the data. The 96-well format also allows for multiple comparisons to be made under identical conditions.

■ EXPRESSION OF SURFACE ANTIGENS ■

CLINICAL INDICATIONS AND IMPLICATIONS

The expression of neutrophil membrane antigens is altered *in vivo* during exudation or after challenge with intravenous endotoxin. Flow cytometric analysis of adhesion molecules on the neutrophil cell surface can indirectly

reflect neutrophil adhesion function. Patients with LAD-1 exhibit a deficit in the expression of the common β_2 integrin, CD18, resulting in deficiency in CD11a, CD11b, CD11c, and CD18²² (Chapter 21).

PRINCIPLES AND INTERPRETATION OF LABORATORY ASSESSMENT

The expression of cell surface antigens is determined on neutrophils stained with specific fluorescent monoclonal antibodies and analyzed by flow cytometric analysis. Neutrophils stained with nonspecific isotype antibodies are used to determine the nonspecific background staining. To determine the expression of circulating neutrophils and avoid artifacts induced by neutrophil isolation, an aliquot of whole blood can be stained with the appropriate antibody prior to lysis of the erythrocytes. During flow cytometric analysis, the neutrophils are easily differentiated using their forward light scatter and side scatter to gate on the neutrophil population. Since very little blood is needed ($100 \mu\text{l}$) for each antigen, neutrophils can be stained with a panel of antibodies to many relevant surface antigens so that a more complete representation of surface antigen expression on neutrophils can be obtained. The panel should include the β_2 integrins (CD11a, CD11b, CD11c, and CD18), selectins (CD62L), Fc γ receptors I, II, and III (CD64, CD32 and CD16), leukosialin (CD43), the common leukocyte antigen (CD45), and markers for the specific granules (CD67) and azurophilic granules (CD63). During exudation, the expression of CD11b and CD18, is increased over that observed in peripheral neutrophils, while the expression of CD43 (leukosialin) and CD62L is markedly reduced.

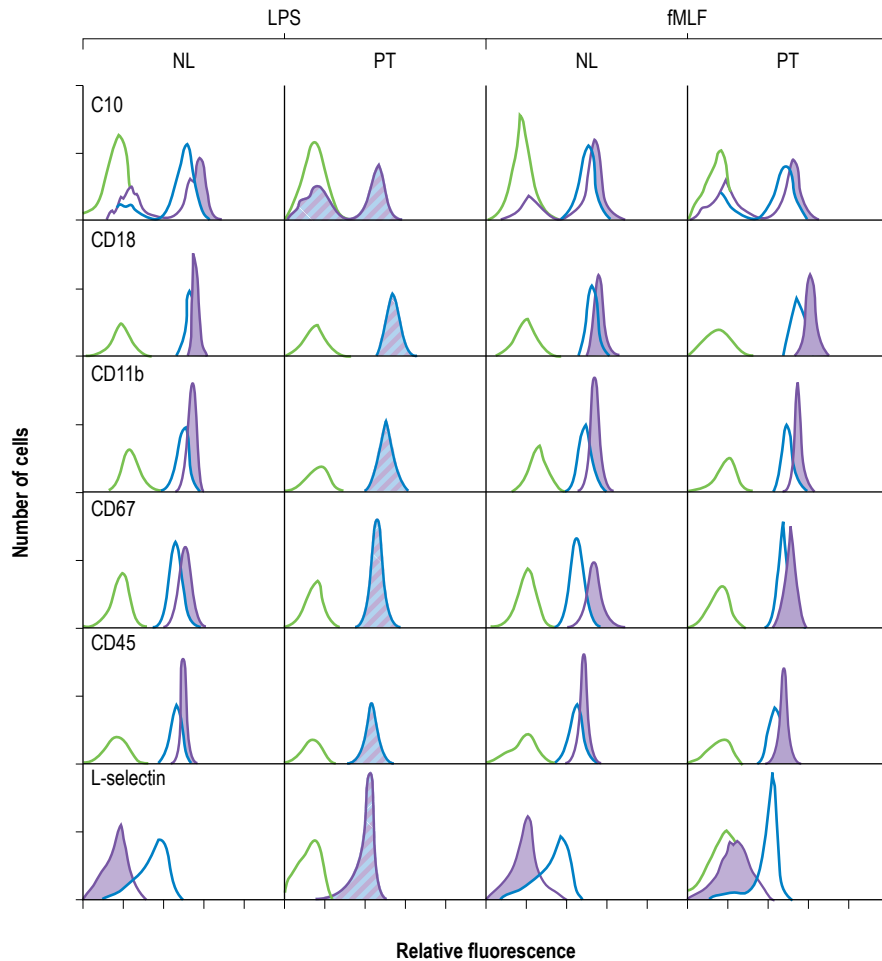

Fig. 99.2 Upregulation of neutrophil surface antigen expression. Neutrophils ($2.5 \times 10^6/\text{ml}$ HBSS + 10% AB sera) isolated from a normal subject (NL) or from a patient with an interleukin-1 receptor-associated kinase-4 (IRAK-4) mutation (PT) were treated with either lipopolysaccharide (LPS: 100 ng/ml) or formyl-methionyl-leucyl-phenylalanine (fMLF: 0.1 μM) for 30 minutes at 37°C. The cells were washed and stained with C10 (an antibody that demonstrates neutrophil heterogeneity), CD18, CD11b (antibodies to β_2 integrins), CD67 (a specific granule marker), CD45 (the common leukocyte antigen), and L-selectin. The green lines represent the isotype control, blue lines represent control neutrophils, and purple lines represent stimulated cells. Differences between control and stimulated cells have been shaded. (From Kuhns DB, Long Priel DA, Gallin JI. Endotoxin and IL-1 hyporesponsiveness in a patient with recurrent bacterial infections. *J Immunol* 1997; 158: 3959, with permission of The American Association of Immunologists, Inc.)

The expression of surface antigens can also be used to assess the responsiveness of neutrophils to particular ligands such as fMLF and LPS. As shown in Figure 99.2, neutrophils isolated from a patient who has a genetic defect in IL-1 receptor-associated kinase-4 (IRAK-4)²³ exhibit abnormal regulation of surface antigen expression to LPS, but exhibit normal regulation of surface antigen expression to fMLF. Antigen expression can be upregulated because of translocation of latent antigen to the plasma membrane or downregulated because of either internalization or shedding of the antigen.

■ NEUTROPHIL DEGRANULATION ■

CLINICAL INDICATIONS AND IMPLICATIONS

The proteases, acid hydrolases, and inflammatory mediators released from storage granules in the neutrophils can mediate bacterial killing, tissue damage, healing, and immune regulation. Lactoferrin that is released from specific granules can chelate iron, resulting in a bactericidal or bacteriostatic effect. Elevation of plasma lactoferrin is an indication of intravascular activation and degranulation of neutrophils.

PRINCIPLE AND INTERPRETATION OF LABORATORY ASSESSMENT

Stimulation of neutrophils with various secretagogues can result in the release of granular enzymes into the extracellular fluid. Treatment of the neutrophils with cytochalasin b (5 $\mu\text{g/ml}$) disrupts microfilament assembly and facilitates the release of both specific and azurophilic enzymes. Since stimulation of neutrophil degranulation is often accompanied by O_2^- generation and oxidative inactivation of enzymes, both the cell supernatant fluid and the cell pellet should be analyzed to determine the percentage of enzyme released. To differentiate degranulation from cell lysis, release of the cytosolic enzyme lactate dehydrogenase should be monitored simultaneously.

The release of azurophilic granules can be assessed by determination of β -glucuronidase activity. Supernatant fluids or cell extracts obtained from stimulated neutrophils are incubated with 4-methylumbelliferyl- β -D-glucuronide. The reaction is stopped with the addition of ammonium hydroxide/glycine buffer and the fluorescence compared to a standard curve of 4-methylumbelliferone. Alternatively, myeloperoxidase can be determined using commercially available enzyme-linked immunoassays. CD63 is also found in the membrane of azurophilic granules and migrates to the neutrophil surface after stimulation with fMLF in the presence of cytochalasin b.

The release of specific granules can be assessed by determination of lactoferrin levels using an enzyme-linked immunoassay. The carcinoembryonic antigen CD66b (formerly CD67) is found on the neutrophil surface and the specific granules, and its expression on the surface of the neutrophils is increased after stimulation with fMLF or LPS. The secretory granules usually contain proteins that are translocated into the membrane from cytosol during degranulation. Detection of the constituents of secretory granules can be assessed by flow cytometric analysis of the change in expression of surface proteins such as adhesion molecules, and cytochrome b_{558} of the NADPH oxidase.

GENERATION OF REACTIVE OXYGEN INTERMEDIATES

CLINICAL INDICATIONS AND IMPLICATIONS

The release of reactive oxygen intermediates (ROI) such as O_2^- and H_2O_2 is an important component of neutrophils' bactericidal machinery. Neutrophils isolated from patients with chronic granulomatous disease (CGD) have a defect in the NADPH oxidase and are unable to generate ROI, resulting in an oxygen-dependent bactericidal defect (Chapter 21). Microorganisms causing infections in patients with CGD are usually catalase-positive, such as *Staphylococcus aureus* and *Escherichia coli*, but not catalase-negative bacteria, because neutrophils isolated from CGD patients can utilize the H_2O_2 generated by the catalase-negative bacterium to enhance the bactericidal activity. NADPH, the source of reducing potential utilized by the oxidase, is provided by metabolism of glucose through the pentose phosphate pathway.

PRINCIPLES AND INTERPRETATION OF LABORATORY ASSESSMENTS

The production of superoxide (O_2^-) can be detected using the reduction of cytochrome c. Because O_2^- causes a one-to-one stoichiometric reduction of ferricytochrome c to ferrocyanochrome c, the resultant

Fig. 99.3 O_2^- generation from normal subjects, chronic granulomatous disease (CGD) patients, and CGD carriers. Neutrophils ($1 \times 10^6/\text{ml}$ HBSS) were incubated in the presence of 100 μM cytochrome c with phorbol myristate acetate (PMA: 100 ng/ml) for 10 minutes at 37°C. The reaction was terminated by centrifugation at 4°C. Reduction of cytochrome c was monitored at an analytical wavelength of 549.5 nm and a micromolar extinction coefficient of 0.0211. An identical tube containing superoxide dismutase (100 $\mu\text{g/ml}$) served as a blank.

increase in the absorption spectrum at 550 nm can be used to quantitate the production of O_2^- . Superoxide dismutase is added to an identical tube to control for the nonspecific reduction of cytochrome c. However, since cytochrome c is not permeable to the cells, the detection of O_2^- is limited to that released into the extracellular milieu. Neutrophils isolated from normal volunteers produce 0.42 ± 0.67 nmol/ 10^6 neutrophils per 10 minutes under resting conditions. As shown in Figure 99.3, treatment of normal neutrophils with PMA results in 35.92 ± 11.92 nmol/ 10^6 neutrophils per 10 minutes. An estimate of normal O_2^- production over 60 minutes can be obtained by reducing the number of neutrophils in the assay to 2×10^5 . Neutrophils isolated from patients with CGD fail to produce O_2^- in response to PMA in 10 minutes. However, some patients with autosomal forms of CGD have low, but detectable O_2^- production in 60 minutes. Neutrophils isolated from X-linked heterozygous carriers of CGD can yield a full spectrum of O_2^- production, while neutrophils from autosomal recessive carriers of CGD generally yield a normal response. Although the detection of O_2^- by reduction of cytochrome c is useful in the diagnosis of patients with CGD, it cannot be used in the diagnosis of carriers because of the wide spectrum of responses that result

from the degree of X chromosome lyonization. Recent studies have shown that O_2^- determinations sufficiently reliable to diagnose CGD can be obtained from neutrophils isolated from heparinized whole blood that has been stored overnight. Hence, analyses can be performed on blood samples shipped by overnight express. A normal control blood sample should accompany the sample to ensure adequate shipment handling. By 48 hours of storage, however, there are marked reductions in the PMA response and the data are no longer valid.

The extracellular release of H_2O_2 can be measured using horseradish peroxidase-induced oxidation of either phenol red or Amplex red. Polymorphonuclear neutrophil suspensions in the presence of horseradish peroxidase and one of the chromophores are exposed to either PMA or buffer alone. Changes in optical density of phenol red at 600 nm can be determined with a standard microplate reader. Amplex red is a much more sensitive fluorescent chromophore and H_2O_2 -dependent changes in fluorescence can be determined with a fluorescence microplate reader.

The nitroblue tetrazolium (NBT) test is a qualitative assay of O_2^- production. Either whole blood or isolated neutrophils are mixed with NBT in a chamber slide and stimulated with PMA for 15–30 minutes at 37°C. The neutrophils are allowed to settle on the slide. The slide is air-dried, counterstained with 0.1% safranin, and examined under a microscope. The NBT test yields a visual record of the reduction of the NBT dye to the insoluble, blue-black deposits of formazan. Normal neutrophils, but not neutrophils from CGD patients, reduce the yellow dye to black-brown-blue aggregates in the cells (Fig. 99.4). Because of the random inactivation of the X chromosome, X-linked carriers of CGD exhibit both NBT (+) and NBT (–) neutrophils. The percentage of NBT (+) neutrophils in X-linked carriers of CGD ranges from 5% to 95%. The drawback of the NBT test is the manual counting necessary to obtain an accurate reflection of the percentage of positive cells. The NBT can be used to diagnose X-linked carriers of CGD but cannot differentiate autosomal carriers from normal subjects.

An alternative to the NBT test is a flow cytometric assay using the dye, dihydrorhodamine-1,2,3.²⁴ Neutrophils are loaded with the non-fluorescent dye, and then stimulated with PMA for 15 minutes at 37°C. The H_2O_2 produced oxidizes the dye and results in increased fluorescence, detectable with a flow cytometer. Catalase is added to prevent cell-to-cell diffusion of H_2O_2 . Since dye is localized to the cytoplasm, and catalase is present in the extracellular fluid, the dihydrorhodamine-1,2,3 assay detects the intracellular production of reactive oxygen metabolites. As shown in Figure 99.5, stimulation of normal neutrophils (A) with PMA results in a two-log shift in the fluorescence intensity. Neutrophils from an X-linked carrier of CGD (B) exhibit mosaicism with a negatively stained (abnormal) population and a brightly stained positive population. Neutrophils from a patient with X-linked CGD that lack *gp91 ϕ ox* (C) express little increase in fluorescence while neutrophils from a patient with a deficiency in *p47 ϕ ox* exhibit a slight increase in fluorescence. The major advantages of the dihydrorhodamine-1,2,3 assay are the sensitivity, the signal-to-noise ratio, and the ease of counting a large number of cells. Moreover, it has been shown that the dihydrorhodamine-1,2,3 assay yields reliable results on ethylenediaminetetraacetic acid (EDTA) or heparin-treated blood samples that have been stored overnight. In general, more than 90% of the neutrophils from the control blood samples will exhibit increased dihydrorhodamine-1,2,3 fluorescence. For this same reason, however, overnight samples should not be used

Fig. 99.4 Nitroblue tetrazolium tests from normal subjects, chronic granulomatous disease (CGD) patients, and CGD carriers. Neutrophils (1×10^6 /ml HBSS) were incubated in the presence of nitroblue tetrazolium (1 mg/ml) and phorbol myristate acetate (PMA: 100 ng/ml) for 30 minutes at 37°C in a slide chamber. The slide was washed twice with HBSS and counterstained with safranin O. Two hundred cells were manually counted using a microscope and scored as the percent nitroblue tetrazolium (+).

to rule out X-linked heterozygosity since a highly lyonized CGD carrier (> 90%) could yield similar results.

■ BACTERICIDAL ACTIVITY ■

CLINICAL INDICATIONS AND IMPLICATIONS

Assessment of bactericidal activity is a general test that encompasses a broad spectrum of neutrophil function. To show normal bactericidal activity, the neutrophil must be able to recognize and ingest bacteria, and then activate a potent microbicidal response that may include both oxidative and nonoxidative mechanisms.

PRINCIPLES AND INTERPRETATION OF LABORATORY ASSESSMENT

Challenging neutrophils with viable bacteria at a fixed bacteria:neutrophil ratio is a useful assay to assess the ability of neutrophils to recognize, ingest, and kill bacteria. In our laboratory, we typically use *Staphylococcus aureus*, substrain 502A. The bacteria are suspended in trypticase soy broth and grown in a shaker water bath at 37°C, monitoring growth until the bacteria are in log phase. In order to add a known number of bacteria, preliminary studies should be performed to determine the number of viable bacteria (i.e., colonies) versus the $OD_{650\text{ nm}}$. In our laboratory, an $OD_{650\text{ nm}}$ of 0.250 yields $0.8\text{--}1 \times 10^8$ bacteria/ml.

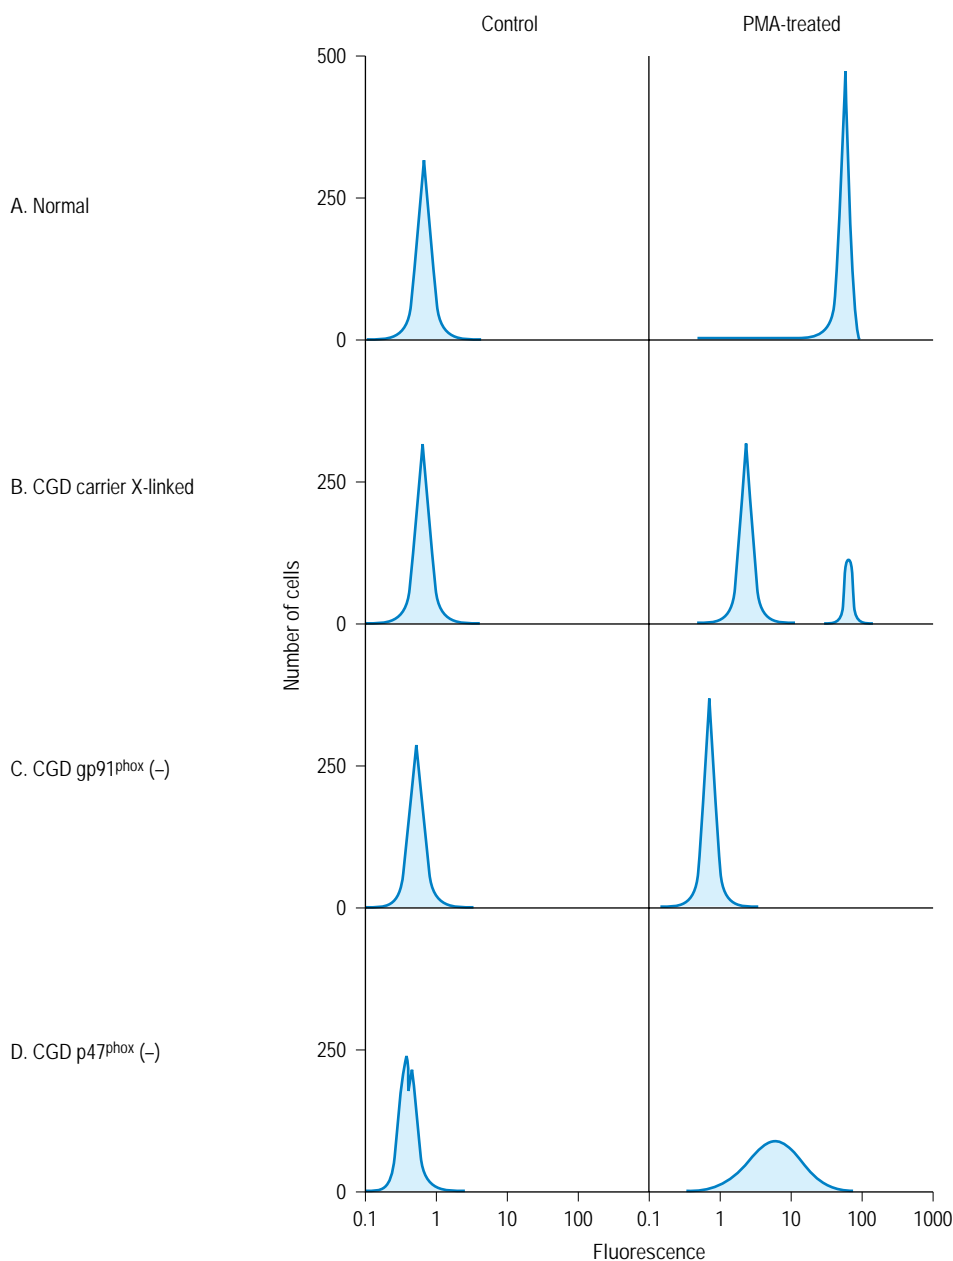

Fig. 99.5 Flow cytometric analysis of dihydrorhodamine staining. Whole blood (1.2 ml with ethylenediaminetetraacetic acid (EDTA) as anticoagulant) collected from a normal subject (A), an X-linked chronic granulomatous disease (CGD) carrier (B), a gp91^{phox} CGD patient (C), and a p47^{phox} CGD patient (D) was lysed using an ammonium chloride–potassium bicarbonate solution. The remaining leukocytes were resuspended in HBSS and incubated with dihydrorhodamine-1,2,3 (100 μ M) for 5 minutes at 37°C. The cells were then incubated an additional 15 minutes at 37°C with either buffer (control) or phorbol myristate acetate (PMA: 400 ng/ml). The cells were immediately analyzed by flow cytometric analysis. Neutrophils were gated using forward light scattering and right-angle light scattering. The analyses presented represent 5000 events within the gated area.

Since neutrophils do not directly recognize bacteria but instead recognize the opsonins (immunoglobulins, complement C3b and C3bi), the assay requires the presence of serum to provide opsonic activity. A pool of freshly frozen AB sera isolated from at least 10 donors yields good results in our hands. Commercially available pools of AB sera have proven less satisfactory, presumably because of losses in complement and opsonic activity during processing. Neutrophils in the presence of human sera and viable bacteria are incubated at 37°C for 90–120 minutes on an end-over-end rotator. Control reactions such as bacteria alone and bacteria with sera alone are included in the study to exclude the possibilities of serum bactericidal activity or poor bacterial viability. At indicated times, an aliquot of the neutrophil suspension is lysed in distilled water to release viable bacteria. A fraction of the lysate is added to a Petri dish, mixed with melted trypticase soy agar, and then allowed to solidify. The plates are incubated for 48 hours in a 37°C incubator and bacterial colony formation is enumerated by either manual counting or image analysis. The data presented are percent killing of the original bacterial challenge. At a low (< 4 bacteria/neutrophil) target:effector ratio, neutrophils kill > 90% of the bacteria. However, increasing the bacterial challenge reduces the efficiency of bacterial killing. Challenge of neutrophils with a low target:effector ratio may be useful in identifying those patients with a marked defect in the ability to kill, while challenge with a higher ratio may be useful in identifying those patients with more subtle defects. Recently, it was reported that lysis of the neutrophils in a more basic solution results in more efficient disruption of the cells and more effective dispersion of the bacterial particles.²⁵ These authors suggest much of the bactericidal activities previously reported may be overestimated and demonstrate more marked bactericidal defects in patients with CGD and myeloperoxidase deficiency.

DETERMINATION OF NADPH OXIDASE PROTEIN DEFECT BY WESTERN BLOT ANALYSIS

CLINICAL INDICATIONS AND IMPLICATIONS

The NADPH oxidase consists of two membrane components, p22*phox* and gp91*phox*, three cytosolic components, p47*phox*, p67*phox*, and p40*phox*, and several guanosine triphosphate (GTP)-binding proteins. CGD is characterized by defects in any one of four of these components – p22*phox* (~5% of CGD patients), p47*phox* (~25% of CGD patients), p67*phox* (~5% of CGD patients), and gp91*phox* (remaining 65% of CGD patients) (Chapter 21).

PRINCIPLES AND INTERPRETATION OF LABORATORY ASSESSMENTS

The severity of CGD may be related to the specific protein defect. Determination of the specific protein defect in CGD by western blot analysis also provides direction for determination of the specific genetic defect as well as enabling appropriate genetic counseling for the extended family. A validated normal control is included on each gel for band identification and intensity comparisons. In addition, a typical gp91*phox* CGD is included on each blot to insure adequate development of p22*phox*. Typical *phox* protein band patterns are presented in Figure 99.6. Patients with p47*phox* CGD are Western blot-negative. Patients with p67*phox* CGD are generally Western blot-negative; however, we

Fig. 99.6 Determination of NADPH oxidase protein defect by Western blot analysis. Frozen, diisopropylfluorophosphate (DFP)-treated neutrophil pellets (5×10^6 cells) were resuspended in polyacrylamide gel electrophoresis (PAGE) sample buffer and sonicated to break up the DNA. One million cell equivalents were loaded into each lane (10% PAGE gels for p47*phox* and p67*phox*, 4–12% gradient polyacrylamide gel electrophoresis (PAGE) gels for p22*phox* and gp91*phox*). A validated normal control was run on each gel for quality control. The gels were transferred to nitrocellulose, blocked with 5% powdered milk, and incubated overnight with specific antibodies to the *phox* proteins. The blots were washed, incubated with peroxidase-labeled secondary antibody, and developed with a color reagent. The blots were scanned for permanent storage and a composite figure was created using the relevant bands from each blot. The lanes are identified by the specific protein defect and, for gp91*phox*, the type of mutation.

have analyzed one patient with a missense mutation in p67*phox* who is Western blot-positive. Because p22*phox* and gp91*phox* exist as a membrane complex, patients with a defect in p22*phox*, in general, are Western blot-negative for both p22*phox* and gp91*phox*. In contrast, defects in gp91*phox* yield more variable results. In general, patients with nonsense defects in gp91*phox* exhibit low but detectable levels of p22*phox*. Patients with missense mutations in gp91*phox* that yield detectable gp91*phox* protein exhibit proportionately higher levels of p22*phox*. Neutrophils isolated from overnight samples can be used to diagnose p47*phox* deficiency because of the stability of the protein. However, detection of other *phox* protein defects in overnight samples can be more problematic because of proteolysis of p67*phox* and the gp91*phox*:p22*phox* complex.

Assessment of human allergic diseases

Robert G. Hamilton

100

TOTAL SERUM IGE

Human allergic disease comprises a spectrum of IgE-mediated immediate-type hypersensitivity reactions that manifest as reactions in the skin (urticaria, dermatitis), respiratory tract (asthma or rhinitis), gastrointestinal tract and, in their most extreme condition, systemic anaphylaxis. These reactions are precipitated by exposure of a genetically predisposed and sensitized individual to a variety of environmental substances that are ubiquitous and usually well tolerated by most healthy individuals. This chapter reviews the principles and performance characteristics of analytical methods used in the diagnosis and management of individuals with allergic disease. It examines *in vivo* and *in vitro* methods for the quantification of total and allergen-specific IgE. Other analytes used in the diagnostic work-up and management of the allergic patient are discussed including total 'free' IgE, mast cell tryptase, eosinophil cationic protein, precipitating IgG antibodies, and the environmental assessment of aeroallergens in indoor environments.

BIOLOGICAL PROPERTIES OF IGE

In 1921, Prausnitz and Kustner (PK)¹ reported that an intradermal injection of serum from an allergic individual into the skin of an unsensitized (nonallergic) individual, followed 24 hours later by injection of specific antigen into the same skin site, induced local itching and swelling surrounded by a zone of erythema. This passively transferred allergic or *PK reaction* reached a maximum within 10 minutes, persisted for about 20 minutes, and gradually disappeared. The antibody mediating this reaction was shown to be thermolabile, losing its sensitizing activity after heating serum at 56°C for several hours. In 1967, this antibody was identified as a fifth human immunoglobulin isotype and designated IgE²⁻⁴ (see also Chapter 4).

Serum IgE concentrations are the lowest of the five human immunoglobulin isotypes (0–0.0001 g/L, 0.004% of the total adult serum immunoglobulin).⁵ Approximately 50% of IgE is localized in the extravascular space. Its short biological half-life in peripheral blood of 1–5 days is due primarily to a relatively high fractional catabolic rate (71% intravascular pool catabolized/day). IgE does not pass the placenta or activate the classic complement pathway. Its reagenic (mast-cell

sensitizing) activity is dependent upon its ability to bind to the α chain of the high-affinity IgE Fc- ϵ receptor (α -Fc ϵ RI) that resides on the membrane surface of basophils and mast cells. The interaction between IgE Fc and the α -Fc ϵ RI is blocked by the therapeutic subcutaneous administration of omalizumab (a humanized IgG₁- κ anti-IgE Fc), as discussed below.

TOTAL SERUM IGE

The concentration of IgE in the serum is highly age dependent.⁵ Cord serum IgE concentrations are low, usually <2 kU/l (<4.88 μ g/L), because IgE does not readily cross the placenta. Serum IgE levels progressively increase in healthy children up to the age of 10–15 years. The rate of this rise towards adult levels is slower than that of IgG but comparable to the observed rise in IgA. Atopic infants have an earlier and steeper rise in serum IgE levels during their early years compared to age-matched non-atopic controls.⁶ Total serum IgE gradually declines in an age-dependent manner from the second to the eighth decades of life.

Clinically, a patient's serum IgE level should be compared to reference intervals established with sera from an age-stratified, healthy skin test-negative (nonatopic) population such as the one reported by Barbee et al.⁶ After age 14, serum IgE levels >333 kU/l (>800 μ g/L) are considered abnormally elevated and strongly associated with atopic disorders, such as allergic rhinitis, extrinsic asthma and atopic dermatitis. Extreme elevations in serum IgE are commonly observed in parasite infections and are necessary for the diagnosis of the hyper-IgE (Jobs) syndrome. Normal or low total IgE levels in some individuals with asthma suggest that IgE-mediated mechanisms play only a minor or insignificant role in the pathogenesis of their condition. Low total serum IgE levels can thus support the diagnosis of nonallergic (intrinsic) asthma and help to exclude bronchopulmonary aspergillosis. The reported overlap between IgE levels in atopic and nonatopic populations, however, is considerable.⁶⁻⁸ Thus although an elevated serum IgE can be useful in confirming the clinical diagnosis of allergic respiratory or skin diseases, a low or normal value does not eliminate the possibility of an IgE antibody-mediated mechanism. This is illustrated by the

observation that a group of adults with allergic asthma had a mean serum IgE level of 1589 ng/mL (range 55–12750 ng/mL), with only about half of them having IgE concentrations >800 ng/mL. In contrast, approximately 90% of patients with atopic dermatitis had elevated total serum IgE levels (mean 978 kU/L, range 1.3–65208 kU/L, where 1 IU=2.44 ng). Parasitic infections, selected immunodeficiency states, cancer (Hodgkin's disease, bronchial carcinoma), rheumatoid arthritis, liver disease and atopic dermatitis (eczema) are other disease states that have been associated with a dysregulation of total serum IgE levels. The total serum IgE must therefore be interpreted carefully within the relevant clinical context for each patient.

Owing to the wide overlap between atopic and nonatopic individuals, total serum IgE measurements had largely been supplanted in the diagnosis of allergic disease by the quantification of allergen-specific IgE antibody. However, this changed when IgE became the focus of a novel therapeutic intervention that involved the subcutaneous administration of anti-IgE antibodies specific for the region on the heavy chain of IgE that interacts with α -Fc ϵ R1.⁹ A recombinant, humanized IgG₁- κ monoclonal anti-human IgE Fc (omalizumab) was licensed in 2003 for the treatment of moderate to severe persistent allergic asthma based on the strategy of blocking IgE binding to the α -Fc ϵ R1. The binding of omalizumab to IgE *in vivo* reduces both the number of free IgE molecules able to interact with the α -Fc ϵ R1 and the number of Fc ϵ R1 receptors on the surface of effector cells. The consequence is a reduction in mediator release and allergy symptoms following allergen exposure.¹⁰ Because dosing of omalizumab is dependent on the pre-treatment level of total serum IgE to achieve the desirable molar ratios of omalizumab to IgE of between 10:1 and 50:1, the measurement of total serum IgE has reclaimed a level of importance in the management of allergic disease using omalizumab.

■ ALLERGEN-SPECIFIC IGE ■

In contrast to total serum IgE, the presence of allergen-specific IgE antibody on basophils or skin mast cells or in the serum is highly predictive of an individual's propensity to exhibit an allergic response upon re-exposure to that allergen. Before its identification as a novel immunoglobulin in 1967, IgE was only detectable with *in vivo* bioassays (skin test, bronchial or nasal provocation tests). Purification of IgE myeloma protein and the subsequent production of antisera specific for IgE led to the development of the first *in vitro* assay (radioallergosorbent test or RAST) for the detection of allergen-specific IgE antibody in serum.^{4,11} Since then, many commercial variants based on the original noncompetitive cellulose paper disc solid-phase radioallergosorbent test design have been developed.

A number of historical studies have compared the diagnostic sensitivity and specificity of *in vivo* and the early *in vitro* assays in the diagnosis of human allergic disease. Such inter-method comparisons, albeit limited in their scope, have shown that the presence of IgE antibody as measured by serologic immunoassay methods usually agreed well with the presence of IgE detected in leukocyte and mast-cell histamine release assays, and provocation tests such as the skin test, food challenge and inhalation provocation test.¹² However, these early studies emphasized the important issue that detection of IgE antibody either *in vivo* or *in vitro* should be considered at best a confirmatory measurement of sensitization that

supports the diagnosis of allergic disease once a patient's medical, family and environmental histories identify a temporal association between allergic symptoms and allergen exposure. The clinical importance of differences in diagnostic sensitivity between skin test and serologic detection of IgE antibody may be less important for patients with allergies to inhaled (pollen, dust mite and epidermal) allergens than in those facing life-threatening anaphylactic reactions caused by Hymenoptera stings, drug administration or occupational exposure to natural rubber latex allergen. In these latter cases, skin tests are preferable to *in vitro* immunoassay analyses for the detection of allergen-specific IgE antibodies.¹³ Immunoassay analyses of IgE antibody in serum may, however, be helpful in certain cases where the patient has taken antihistamines, β -receptor stimulants or high-dose steroids, which can reduce the provocation test's measured response in children, pregnant women and elderly patients, in whom skin testing may not be well tolerated; and when dealing with allergens (e.g., foods, molds) where commercial extracts can be highly variable or labile.¹⁴

■ DIAGNOSTIC METHODS ■

A combination of *in vivo* provocation and *in vitro* laboratory tests may be useful as confirmatory tests to support the clinical diagnosis of allergic disease. The actual tests selected will ultimately depend on the nature of the disease process under investigation (e.g., extrinsic asthma, urticaria/angioedema, rhinitis/sinusitis or anaphylaxis).

■ INITIAL CLINICAL LABORATORY TESTS ■

Following a medical history and physical examination, the patient who is suspected of having allergic disease may undergo several preliminary blood tests. A complete blood count and/or a total blood eosinophil count, if performed, should be obtained before any systemic corticosteroids or epinephrine are administered. Normal whole blood eosinophil levels range from 0 to 500 cells/mm³. Children generally have higher normal levels (mean 240 cells/mm³, 95% confidence limit=0–740 cells/mm³), with peak levels occurring at 4–8 years of age. Most laboratories consider a differential white blood cell count with an eosinophil level >5–10% of the total white cell count to be abnormal. Blood, sputum and nasal secretion eosinophilia is characteristic of asthma, whether or not allergy is present. In a bronchitic sputum specimen, neutrophils predominate. A neutrophilic nasal discharge is characteristic of sinusitis. Other laboratory tests that may be ordered include pulmonary function tests and a chest X-ray or sinus CT, as indicated.

■ IN VIVO PROVOCATION TESTING ■

Both the skin test and nasal/bronchial/gastrointestinal provocation tests are useful diagnostic tools for the confirmation of immediate-type hypersensitivity reactions associated with allergic disease, and in the identification of the offending allergens in the work-up for avoidance, or management with pharmacotherapy, immunotherapy or anti-IgE therapy.

SKIN TESTS

Guerin and Watson¹⁵ described a three-phase response that occurs in the skin during an immediate-type skin test reaction following the administration of a stimulus (allergen or histamine-positive control). First, a bluish-white area appears that involves the constriction of capillaries and which typically disappears within minutes. Second, an erythemic peripheral halo or flare appears as a result of arteriole dilatation. Finally, a circular urticarial papule or wheal is observed, as a result of extravasation of plasma into the skin, which is generally maximal by 15–20 minutes. The immediate wheal and flare reaction can be followed by a late-phase reaction 5–6 hours later that appears as a poorly defined edema-like reaction which usually disappears by 24 hours. An allergen extract can be administered either by a prick/puncture or by intradermal injection.¹⁶

Puncture skin testing involves placing a drop of allergen extract on the skin of the forearm or back and the introduction of allergen into the epidermis by a needle puncture. A variety of single-point, multipoint and bifurcated needles have been used.¹⁷ After the prick or puncture, the excess allergen is removed by blotting with tissue paper or gauze. An immediate reaction (wheal and erythema) is read at 15–20 minutes as it reaches its maximum size. Care is taken to space individual tests sufficiently far from each other as not to produce overlapping erythema. Because of the direct skin irritation, with some crude allergen extracts bleeding can produce false positive results.

The intradermal skin (ID) test is 1000–10 000 times more sensitive by concentration than is the puncture test. A 0.01–0.05 mL volume (optimally 0.02 mL) of diluted allergen extract in a 0.5–1.0 mL syringe is injected intracutaneously through a 26–27 gauge needle. An 0.02 mL injection will initially produce a superficial 2–3 mm diameter bleb. Like the puncture test, the ID skin test is read at 15–20 minutes, when the reaction is maximal. Dilutions of extract >1:1000 w/v are commonly used to minimize false positive irritation and the potential for systemic reactions. Subcutaneous administration of the allergen may lead to a false negative result. The volume of allergen extract that is injected only slightly influences the size of the wheal and flare reaction, whereas its concentration is the most important determinant of final ID skin test results. Intradermal testing allows an investigator to perform a skin test titration to determine quantitatively the patient's skin sensitivity. For serial titration, the same volume (e.g., 0.02 mL) of 3–10-fold serial dilutions of allergen extract is injected into different sites in the skin and the concentration of allergen required to produce a wheal or erythema of a defined mean diameter (e.g., 8 mm wheal) is interpolated. The higher the concentration of allergen required to induce the defined size of wheal or erythema, the less sensitive the patient is to that allergen preparation.

Figure 100.1 shows the relationship between the ng/mL level of *Dermatophagoides pteronyssinus* (*Dpt*, dust mite) specific IgE antibody in sera from 30 dust mite-allergic subjects, as measured in serum by an *in vitro* assay, and the ID skin test midpoint *Dpt* allergen extract titer required to produce an 8 mm wheal in the same individual. Using the same *Dpt* extract in both tests, a higher degree of skin sensitivity (i.e., lower titer of antigen required to induce an 8 mm wheal) was strongly correlated ($r^2=0.77$, $P<0.001$) with higher serum IgE antibody levels in those with the higher levels of skin sensitivity (<10 ng/mL midpoint). Figure 100.2 shows the strong correlation in wheal size that is observed in the same *Dpt*-allergic patients receiving the same dust mite extract in a single puncture skin test and a midpoint intradermal skin test titration.

Fig. 100.1 Relationship between IgE anti-*D. pteronyssinus* (*Dpt*) in the skin (x-axis, intradermal skin test titration; ng/mL of *Dpt* required to produce an 8mm wheal) and in the serum (y axis, ng/mL of IgE anti-*Dpt* as measured by RAST; sensitivity = 2 ng/mL). These results were obtained by testing the skin and serum of 30 dust mite-allergic individuals with varying degrees of clinical sensitivity using the same *Dpt* extract in both the RAST and the ID skin test titration study. A lower 'titer' of antigen required to induce an 8 mm wheal (e.g., higher degree of skin sensitivity) was strongly correlated ($r=0.77$; $P<0.001$) with a higher serum IgE antibody level in individuals with the higher level of skin sensitivity (<10 ng/mL midpoint). Less sensitive patients (titers >10 ng/mL *Dpt*) had lower levels of serum antibody (2–15 ng/mL) that did not relate well with skin sensitivity.

Both the puncture and the ID skin test procedures produce a maximal wheal and flare size by 15–20 minutes, which is measured with a millimeter ruler or caliper. The maximal diameter and the midpoint perpendicular diameter are averaged to generate an index. A permanent record of the skin reaction can be made by applying adhesive cellulose tape over the wheal and flare skin area, which has previously been outlined with a felt-tip or ballpoint pen. Using a single concentration of allergen, the ID skin test can be graded according to one of several reported systems^{16, 17}(Table 100.1). Alternatively, a midpoint titer may be interpolated from a skin test titration including serial three or 10-fold dilutions of the allergen extract. Some investigators prefer to use the erythema (flare) size rather than the wheal size obtained during titration studies because the slope of the flare's regression line with dose is steeper.¹⁸ The strong relationship between the size of the intradermal erythema and wheal observed with the mean of 304 duplicate skin tests is shown in Figure 100.3. This relationship is useful to know, because in many dark-skinned subjects the erythema is difficult or impossible to assess.

Fig. 100.2 The wheal size in millimeters at a single dose of *Dpt* allergen administered in a puncture skin test compared to the titer or ng/mL of the same *Dpt* allergen obtained in an ID skin test titration on the same 26 dust mite-allergic patients to produce an 8 mm wheal. These data indicate that the wheal size obtained with a single dose of allergen by the less labor-intensive puncture skin test is as predictive ($r^2=0.72$, $P < 0.001$) of relative patient sensitivity as the more technically complex intradermal skin test titration study, which involves the administration of seven increasing concentrations of the same allergen into different skin sites.

BRONCHIAL AND NASAL PROVOCATION TESTS

Bronchial and nasal provocation challenges are performed primarily as research procedures to identify a relationship between an inhaled substance and a change in the patient's bronchial or nasal physiology. Bronchoprovocation studies with methacholine can also be useful in the diagnosis of difficult cases of asthma. The bronchoprovocation procedure involves the administration of either methacholine or histamine via a calibrated nebulizer, starting at doses of 0.05–0.1 mg/mL and doubling the concentration up to 10–25 mg/mL. Alternatively, allergen extracts can be administered in increasing doses. Pulmonary function is monitored after each dose. A positive response is usually defined as the concentration of agonist that results in a drop in the forced expiratory volume per second (FEV₁) of 20% or more from the baseline (which must be >70% of that predicted for valid interpretation). More extensive details regarding the methods and interpretation of bronchial challenges are presented elsewhere.¹⁹

Nasal provocation in its simplest form involves the controlled administration of buffer (human serum albumin–saline) or increasing concentrations of allergen into a washed nasal passage. The symptoms (e.g., number of sneezes) induced and/or mast cell mediators released

Fig. 100.3 Correlation plot of the mean wheal (x-axis) and erythema (y axis) in millimeters for the mean of 304 duplicate intradermal skin tests to dust mite (*D. pteronyssinus*) obtained in a population of dust mite-sensitive individuals. The relationship is highly correlated ($r=0.82$, $P < 0.001$) in grades 0–3+, indicating that either can be used to judge the degree of intradermal skin sensitivity. In highly allergic individuals (>35 mm erythema), however, the slope declines dramatically, indicating that wheal size may be more discriminating than erythema.

into nasal lavage fluids (e.g., TAME esterase and histamine) after each concentration of allergen indicates the relative level of sensitivity to that allergen. Nasal airway resistance is a less satisfactory end-point because of high intrinsic variations. Details of the procedure and applications can be found elsewhere.²⁰

A hooded exposure chamber has been described for simultaneous nasal and bronchial challenges as a diagnostic procedure for assessing occupationally induced latex allergy.²¹ The challenge involves bathing the subject's conjunctiva and upper and lower airways with air alone, placebo (untreated) cornstarch, and then graded concentrations of latex cornstarch, each for 3-minute intervals separated by 15 minutes. Following each challenge the peak expiratory flow rates (PEFR) and chest and rhinoconjunctival symptoms scores are monitored.²² This procedure has been particularly useful in problematic diagnostic cases involving a discordant clinical history and IgE anti-latex skin test and/or serological test result.

DOUBLE-BLIND PLACEBO-CONTROLLED FOOD CHALLENGE

Food-induced gastrointestinal reactions (e.g., nausea, colic, vomiting and diarrhea) may occur minutes to hours after the consumption of food allergens by a sensitized individual.²³ Commonly eaten foods

Table 100.1 Grading system for puncture and intradermal skin testing using histamine as a reference^{a, b} (Modified from Norman PS. Skin testing. In: Middleton E, Ellis EF, Reed CE, eds. Allergy: principles and practice, 2nd edn. St Louis: CV Mosby, 1982, with permission from Elsevier.)

Skin testing grading system		
Grade or Class	Wheal size (mm)	Erythema size (mm)
0	No discernible wheal	
1+	$\leq \frac{1}{2} \times$ histamine wheal	
2+	$> \frac{1}{2} \times$ histamine and $< 1 \times$ histamine wheal	
3+	= size of histamine wheal ± 1 mm	
4+	$> 1 \times$ histamine wheal and $< 2 \times$ histamine wheal	
5+	$> 2 \times$ histamine wheal	

Alternative skin test grading system for intradermal skin testing only involving interpretation of wheal and erythema responses ^b		
0	<5	<5
+/-	5-10	5-10
1+	5-10	11-20
2+	5-10	21-30
3+	10-15	31-40
4+	> 15 with pseudopods	41-50

that are known to contain potent allergens include cow milk (caseins, β -lactoglobulin, α -lactalbumin), chicken egg white (ovalbumin, ovomucoid, ovotransferrin), cereal grains (wheat, rye, barley, oats), legumes (peanut, soybean, white bean), fish and seafood (shrimp, crabs, lobsters, oysters). Diagnosis of a food allergy begins with a medical history, which includes an assessment of diet diaries and elimination diets as necessary. Skin tests and serological tests for IgE antibody to extracted food allergens and open food challenges with fresh and cooked foods may also be used to confirm sensitization to suspected foods. No evidence is available to indicate that food-specific IgG or IgG₄ antibody levels have any diagnostic value. The double-blind placebo-controlled food challenge (DBPCFC) is considered the definitive diagnostic test for food allergy.^{23, 24} An extensive discussion of the DBPCFC and variables influencing its outcome is presented elsewhere.²³⁻²⁵

In 2001, prospectively collected sera from 100 children and adolescents who had been previously evaluated by a skin test and DBPCFC were analyzed in the Phadia ImmunoCAP system for food-specific IgE antibody.²⁵ The investigators were able to identify a diagnostic level of IgE antibody for egg (7 kIUa/L), milk (17 kIUa/L), peanut (14 kIUa/L) and fish (20 kIUa/L), above which they could predict clinical reactivity in this group with more than 95% certainty. They concluded that by measuring the concentration of food-specific IgE antibody with the ImmunoCAP system, it was possible to identify a subset of children who were highly likely (>95%) to experience a clinical reaction to egg, milk, peanut or fish. Quantitative serological measurements for food-specific IgE antibody may therefore be able to eliminate the need for time-consuming DBPCFCs in a significant number of children who are suspected of having food allergy.

CLINICAL LABORATORY (IN VITRO) TESTING

Most diagnostic allergy laboratories offer a variety of serological tests that can be useful in the diagnosis and management of human allergic disease. Analytes commonly measured in these laboratories include the total serum IgE, allergen-specific IgE, Hymenoptera venom-specific IgG, the venom-RAST inhibition test, and mast cell α and β tryptase. IgG antibody measurements to allergens other than Hymenoptera venom have not been shown to be clinically useful. Basophil histamine release (BHR), although rarely offered as a clinical test because of the requirement for fresh blood, is a useful investigational method that will also be reviewed in this section.

TOTAL SERUM IgE

Of the diagnostic allergy tests that are performed in the clinical immunology laboratory, total serum IgE is currently the only analyte regulated under the US Clinical Laboratory Improvement Amendment of 1988 (CLIA88). Currently five FDA-cleared commercial assays are used by clinical laboratories in the USA to measure the total level of IgE in serum (see College of American Pathologists [CAP] proficiency survey).²⁶ At present, free total IgE measurements for patients receiving omalizumab are only available with research enzyme immunoassays,²⁷ and the clinical utility of free IgE levels in assessing the efficacy of Xolair (anti-IgE) treatment still needs to be confirmed by prospective clinical studies.

Radioisotopes such as ¹²⁵I have been largely replaced by nonisotopic labels such as enzymes (horseradish peroxidase, alkaline phosphatase, β -galactosidase) or fluorophors. The minimum detectable concentration

KEY CONCEPTS

IgE (REAGINIC) ANTIBODY DETECTION

- >> Allergen-specific IgE can be detected in skin test by a puncture or intradermal administration of allergen or in the serum by laboratory-based immunoassays.
- >> In general, the intradermal skin test is more sensitive than a puncture skin test, which is roughly comparable to the best *in vitro* methods for IgE antibody detection in serum.
- >> Because the results of *in vitro* tests for IgE antibody vary considerably between methods, proficiency testing surveys are essential to evaluate performance.
- >> Double-blind placebo-controlled food challenge is the gold standard for definitive diagnosis of food allergies.

of most commercial assays is between 0.5 and 1 $\mu\text{g/L}$. The inter-method agreement of the different commercial IgE assays is excellent (e.g. inter-method coefficients of variation [CVs] typically <10% for serum IgE levels = 30 kIU/L).²⁸ Nonatopic age-adjusted reference intervals for total serum IgE must be used for normative interpretation.⁵

ALLERGEN-SPECIFIC IgE

Laboratories performing clinical diagnostic allergy testing need to use an FDA-cleared procedure and perform successfully in an external diagnostic allergy proficiency survey (e.g., CAP SE Survey²⁶). Of the 11 earlier versions commercial IgE antibody assays, only three have remained in active use in the USA. The two most widely used (Phadia ImmunoCAP System and Siemens Immulite 2000) are assays that use automated platforms with high-quality control reagents and calibrators. These assays have achieved unsurpassed intra-assay precision and inter-assay reproducibility and a high degree of quantification. Their basic assay design can be traced back to the first IgE antibody assay, the radioallergen sorbent test or RAST, reported by Wide et al. in 1967.¹¹

The most highly variable component of the IgE antibody assay is the allergen-containing reagent. The US Clinical and Laboratory Standards Institute (CLSI) (formerly the National Committee on Clinical Laboratory Standards [NCCLS]) has an established 1997 guideline that is currently being revised.²⁹ It defines the performance characteristics of immunologic assays for human IgE antibodies to specific allergens and provides a glossary of ~400 allergens of clinical interest. Some of these share structurally similar or cross-reactive epitopes, and others possess entirely unique IgE antibody-binding determinants. Allergens as a whole have been conveniently grouped into extracts of weed pollen, grass pollen, tree pollen, animal epidermals, molds, house dust mites, parasites/insects, occupational allergens, drugs, venoms and foods. Among different species of a genus, such as ragweed (e.g., Canyon, Desert, Giant, Short, Silver, Southern, Western), there is extensive allergenic cross-reactivity. Extensive allergenic cross-reactivity has also been documented within particular pollen groups, such as the grasses (June, Brome, Timothy, Perennial Rye, Fescue, Orchard, Red Top, Salt, Sweet Vernal, Velvet). In contrast, certain grass pollens, such as those produced by Bermuda Grass, Johnson Grass and cultivated corn, oat and wheat, are minimally cross-reactive (allergically distinct). Variations in the allergenic content of

source materials, the extraction process from the raw source material, allergen-reagent manufacturing methods, differential binding to various allergosorbent supports, instability during storage, heterogeneity of internal reference allergen standards, and differences in characterization procedures (antisera, assays) make the production of reproducible allergens for *in vitro* use a challenge. Table 100.2 lists the most commonly requested allergen specificities that are available as diagnostic products.

The second attribute that varies widely among commercially available IgE antibody assays is the unitage that provides an estimate of IgE antibody content in a serum. The CLSI guideline²⁹ has been instrumental in establishing expectations for the units reported from IgE antibody assays. Because clinically used allergen-specific IgE antibody immunoassays are now calibrated using a heterologous total IgE calibration curve³⁰ traceable to the WHO 75/502 IgE international reference preparation, quantitative interpolated results should be reported in kIUa/L. At least for one IgE antibody assay (the ImmunoCAP system), there is evidence that absolute quantification has been achieved. Using IgE chimeric antibodies with adsorption and depletion analysis, 1 kIUa/L of allergen-specific IgE antibody has been shown in this assay to be equivalent to 1 kIU/L of total serum IgE.³¹

Some investigators have proposed that IgE antibody to 10–15 aeroallergen specificities may account for much aeroallergen-related disease. Although the particular 10–15 allergen specificities may vary for children and adults, or for individuals in Europe, Asia and the USA, it has been possible to develop a single ‘multiallergen’ IgE antibody screening test that is highly predictive of the results obtained by a panel of skin tests or *in vitro* IgE antibody tests. In these assays, a panel (e.g., 10–15) of common complex allergen mixtures crossing the aeroallergen groups are insolubilized on a single solid phase (e.g., Phadiatop) or comparable purified native or recombinant allergens are adsorbed onto triplicate dots of a single solid support (silicone chip).^{14,32} These screening assays are useful in confirming the absence of significant atopic disease in individuals suspected of having an intrinsic or nonIgE-mediated disease process. Their negative predictive value as a single test is higher than total serum IgE in identifying nonatopic individuals. Such a test can minimize the need for multiple *in vivo* or *in vitro* allergen-specific IgE measurements in patients with a low clinical probability of atopic disease. The use of such screening tests in unselected populations sometimes generates positive results of questionable clinical significance, however, as IgE antibody responses are more frequent than is symptomatic disease. Most recently, multiple allergens have been adsorbed in single or multiple bands on one nitrocellulose strip and configured in a lateral flow assay cassette analogous to over-the-counter pregnancy type assays.³³ This semi-quantitative ‘point of care’ test is designed for use with a drop of whole blood from a finger stick. It is unclear what impact these lateral flow assays will have on the diagnosis of allergic disease when used by patients or primary care physicians.

The quality of allergen-specific IgE antibody results reported from clinical diagnostic allergy laboratories is not uniformly equivalent.³⁴ For this reason, physicians requesting IgE antibody testing bear some responsibility for determining the quality of the results they receive. In the USA, testing should be performed in a clinical laboratory that is federally licensed for highly complex immunology clinical testing under CLIA-88 (verified by requesting a copy of the federal laboratory license). The requesting physician should inquire about the assay method used, the source of its reagents and how assays are quality controlled by the laboratory.

COMPETITIVE IGE ANTIBODY INHIBITION ASSAY

The soluble allergen, competitive inhibition format of the IgE antibody assay (e.g., ImmunoCAP, Immulite 2000), or its isotopic counterpart (the RAST inhibition assay), has been widely used by researchers, allergen manufacturers and regulators to determine the relative potency of allergen extracts. One practical research application of the IgE antibody inhibition assay has been as a tool for monitoring the concentration of allergens released into environments (e.g., air sampling of airplanes for aerosolized peanut allergen). Latex allergen, for instance, that is released into the air from powdered latex gloves or onto mucosal surfaces from condoms, or the dental use of latex gloves, has been monitored using this assay as manufacturers change their production methods in an effort to reduce leachable allergen content. In the diagnostic allergy laboratory, the competitive IgE antibody inhibition assay has been used analytically to confirm an IgE antibody assay's minimum detectable dose (sensitivity) and nonspecific binding, and to document the allergen specificity of IgE antibody binding as a part of a quality control program.

The one clinical application of the IgE antibody inhibition assay has been as an adjunct to define the appropriate therapeutic composition of venoms for insect sting-allergic patients who have multiple potentially cross-reactive sensitivities and have elected to receive immunotherapy³⁵ (Chapter 93). The primary indication for this test is a strong skin reactivity or a high level of serum IgE antibody to Yellow jacket venom (YJV) and a weak skin reactivity or low level of serum IgE antibody specific for *Polistes* wasp venom (PWV). The structural similarity between vespid and *Polistes* wasp phospholipase A1/B (*Ves g* I; *Pol a* I) and hyaluronidase (*Ves g* II; *Pol a* II) frequently produces IgE antibody cross-reactivity. Sera from 305 Hymenoptera venom-allergic patients with >2 ng/mL of IgE antibody to YJV and PWV were evaluated in the IgE antibody inhibition assay to document its utility. The clinical question for these patients was whether PWV should be included in their venom immunotherapy together with Yellow jacket or mixed vespid venom. Using this procedure, the venom RAST inhibition assay identified one-third (36.4%) of subjects with a primary YJV sensitivity who were candidates for exclusion of PWV from their immunotherapy regimen because their IgE anti-PWV was >95% cross-inhibitable with soluble YJV.³⁵

CLINICAL PEARLS

CLINICAL UTILITY OF HYMENOPTERA VENOM RAST INHIBITION TEST

- >> Useful in identifying venom cross-reactive IgE antibodies and selecting appropriate venoms for immunotherapy.
- >> One-third of venom-allergic patients with concomitant Yellowjacket venom (YJV) and *Polistes* wasp venom (PWV) sensitivity can be treated with YJV alone or mixed vespid venoms, owing to >95% cross-reactive IgE anti-PWV with soluble YJV.

ALLERGEN-SPECIFIC IgG

Allergen injections during immunotherapy are known to enhance the production of specific IgG 'blocking' antibodies. Quantitative measurements of total IgG antibodies or IgG subclass antibodies in studies of allergic rhinitis have not generally correlated with the control of clinical symptoms in individual patients. However, clinically successful immunotherapy is almost always accompanied by high serum levels of allergen-specific IgG.³⁶ In contrast, the presence or levels of IgG antibodies specific for food antigens have shown no correlation with the results of positive double-blind placebo-controlled food challenges.

Allergen-specific IgG antibody measurements may be helpful in determining optimal therapy in patients with Hymenoptera venom sensitivity. In a prospective study, Hymenoptera venom-specific IgG antibodies were monitored in the serum of 109 venom-allergic patients to examine whether IgG antibody levels could predict the risk of a systemic reaction after a sting challenge in patients receiving venom immunotherapy.³⁷ The highest rate of allergic reactions (26%) occurred in patients who had both a venom-specific IgG antibody level <3 μ g/mL and fewer than 4 years of venom immunotherapy.³ Therefore, quantitative venom-specific IgG antibody levels appear to be of value in individualizing the dose and frequency of injections while maximizing the protective effects. The clinical utility of the IgG antibody measurement may be restricted to the first 4 years of venom immunotherapy.

CLINICAL PEARLS

IGG ANTIBODY MEASUREMENTS

- >> Clinically successful aeroallergen immunotherapy is almost always accompanied by high serum levels of allergen-specific IgG.
- >> Quantitative venom-specific IgG antibody levels can be of value in individualizing venom doses and frequencies for patients on immunotherapy for up to 4 years.
- >> Food-specific IgG and IgG4 assay results do not correlate with the results of double-blind placebo-controlled food challenges.

MAST-CELL TRYPTASE

Two types of mast cells have been identified in skin, respiratory and digestive tract connective tissues based on the types of neutral proteases present in their secretory granules. One group contains only tryptase, whereas the other contains both tryptase and chymase³⁸ (Chapter 22). Upon activation of mast cells, these proteases are released in parallel with pre-stored histamine and newly generated vasoactive mediators. Mast-cell tryptase (MW 134 kDa) is a serine esterase with four subunits, each having an enzymatically active site. A resting mast cell contains 10–35 pg of tryptase that is stored attached to heparin. When dissociated from heparin, it rapidly degrades into its monomers and loses enzymatic activity. As basophils are a rather insignificant source of tryptase release, tryptase in serum has been proposed as a marker of mast-cell activation. The concentration of α -tryptase in blood is considered a measure of mast cell numbers. It is estimated by subtracting the measured β -tryptase level from the total serum tryptase concentration. The level of β -tryptase is considered a measure of mast cell activation.

A noncompetitive two-site fluorescent enzyme immunoassay (Phadia, ImmunoCAP) is available to measure total tryptase in serum.³⁹ Total tryptase levels in the serum of healthy (nondiseased) adults average 5 $\mu\text{g/L}$ (range 1–10 $\mu\text{g/L}$). Elevated levels of tryptase (>10 $\mu\text{g/L}$) can be detected in serum from 1 to 4 hours after the onset of systemic anaphylaxis with hypotension.⁴⁰ Baseline levels >20 $\mu\text{g/L}$ suggest systemic mastocytosis. β -tryptase levels <1 $\mu\text{g/L}$ are observed in nondiseased individuals and >1 $\mu\text{g/L}$ indicates mast cell activation. Recommended serum collection times for tryptase quantification range from 30 minutes to 4 hours after the onset of an acute event. Although postmortem specimens are often difficult to analyze for tryptase because of high viscosity related to gross hemolysis, tryptase levels >10 $\mu\text{g/L}$ suggest systemic anaphylaxis as one probable cause of death. Elevated β -tryptase resulting from an insect sting-induced anaphylaxis can peak at more than 5 $\mu\text{g/L}$ by 30–60 minutes after the sting, and then decline with an approximate half-life of 2 hours.⁴¹ This contrasts with histamine, which peaks within 5–10 minutes after an event, and may return to baseline levels in less than 1 hour. Tryptase has also been detected in bronchoalveolar lavage fluid, nasal lavage fluid, tears and skin chamber fluid, but there are currently no clinical indications for such measurements. The diagnostic value of tryptase as a marker of anaphylaxis and mastocytosis is extensively reviewed elsewhere.⁴²

BASOPHIL MEDIATOR RELEASE ASSAYS

Histamine release assay

The potent vasoactive mediator histamine is stored in cytoplasmic granules of basophilic leukocytes and mast cells and released along with other mediators of inflammation in response to both immunologic and nonimmunologic stimuli.^{37, 43} The basophil histamine release (BHR) assay has been particularly useful as a quantitative assay of allergen potency, and as an *in vitro* model for the study of triggering mechanisms of mediator release from basophils. In its most basic form, peripheral blood leukocytes are isolated from a donor and incubated with varying concentrations (e.g., 3–10-fold dilutions) of allergen extract or anti-human IgE as a positive control. Histamine release is complete within 30 minutes, and then histamine in the supernatant is measured by enzymatic, radiometric or spectrophotofluorometric techniques.⁴⁴ Details of the BHR assay are given elsewhere.⁴⁴

Patient sensitivity for a given allergen can be determined with a positive BHR test. The results are highly correlated with those determined by skin testing⁴⁴ and bronchoprovocation.⁴⁵ Although the BHR test has been most widely used in research laboratories owing to its expense, time-consuming nature and the need for fresh blood (<24 hours old), it can be successfully applied to the clinical diagnosis of allergy in selected cases, as the results obtained parallel those of other IgE antibody tests. BHR has also been a useful tool for clarifying discrepancies between skin test and serological IgE antibody test results.

Leukotriene C4 (LTC4) release assay

An assay method for measuring LTC4 released from allergen-activated basophils has been reported as the cellular antigen stimulation test (CAST)–ELISA.⁴⁶ The LTC4 assay is designed for use with either whole blood preparations or washed leukocytes. A number of clinical studies have compared the predictive value of the CAST to skin testing using dust mite, food, Hymenoptera venoms and drugs as challenges. The observed diagnostic sensitivity of the CAST compared to the combination of a clinical history and skin test ranged from 18% with aspirin to 85% for selected food allergens. The reported diagnostic specificity of the CAST in the same studies ranged from 67% to 100%. These data indicate that the CAST assay is not sufficiently sensitive for effective clinical use in the diagnosis of IgE-mediated sensitivities to β -lactam or nonsteroidal anti-inflammatory drugs. Its utility in the diagnosis of sensitization to other allergen specificities appears more promising, but further documentation involving clinical studies is required.⁴⁷

Utility of mediator release assays as diagnostic tests

Despite their unquestioned value as research methods, the basophil histamine and LTC4 release assays are rarely used clinically in the routine diagnosis of human allergic disease. Moreover, it is unlikely that this trend will change in the foreseeable future.

FLOW CYTOMETRY BASOPHIL ACTIVATION ASSAYS

In the late 1990s, basophils were shown to upregulate the expression of a number of surface proteins (e.g., CD45, CD63, CD69 and CD203c) when activated by allergen.^{48–50} CD63 is a member of the transmembrane-4

superfamily that is expressed on basophils, mast cells, macrophages and platelets.⁴⁹ In resting basophils from nonatopic and allergic individuals, CD63 is attached to intracytoplasmic granules. Activated IgE-sensitized basophils express a high density of CD63 on their surface. By quantifying ~500 basophils with gated flow cytometry, the percentage of activated basophils can be identified following a correction for spontaneous CD63 expression. A variety of criteria are used to identify an allergen-induced positive response, such as a stimulation index (allergen-induced/basal ratio) >2. One confounding variable in this analysis is the adherence of CD63-expressing platelets in basophil preparations that can sometimes generate false positive results.

The flow assay stimulation test (FAST) using CD63 as a marker for activation was evaluated using minor determinant mixture, benzyl penicilloyl polylysine, penicillin, ampicillin amoxicillin and cephalosporin as stimulating antigens.⁵⁰ Subjects (n=58) with a history of immediate-type reactions to β -lactam antibiotics or nonallergic controls (n=30) were evaluated in the CD63 FAST and Phadia ImmunoCAP system for drug-specific IgE levels. Relative to the clinical history, the CD63 FAST displayed a diagnostic sensitivity and specificity of 50% and 93%, respectively. Diagnostic sensitivity was marginally increased to 66% by simultaneously using the drug-specific IgE antibody serology result. The study concluded that the CD63 basophil activation test could be helpful in supporting the diagnosis of IgE-mediated allergy to β -lactam drugs when used in conjunction with an additional diagnostic test such as IgE antibody serology.

CD203c, also known as neural cell surface differentiation antigen, E-NIPP3 PD-1 β , 97A6, B10 and gp130rb13-6, is member of the ectonucleotide pyrophosphate phosphodiesterase (E-NPP) family.⁵¹ It is expressed only on IgE-bearing basophils, mast cells and their progenitors, and is upregulated following activation of IgE sensitized basophils with allergen or anti-IgE in a manner similar to CD63. The CD203c-based flow-assay is performed in a manner analogous to the CD63-based assay. Its advantage over CD63 is its restricted expression on basophils in peripheral blood, which minimizes concern about the adherence of platelets that may produce false positive CD63 results. Additionally, there is no need for the use of an additional fluorescent anti-IgE reagent to gate the basophils.

Basophil activation as determined by CD203c expression was studied in Hymenoptera venom patients and healthy controls in which their basophils were activated with anti-IgE or bee/vespid venoms.⁵² Fifteen minutes after stimulation, basophils from 15 wasp-sensitized patients upregulated CD203c expression from 4.2- to 13.5-fold. Moreover, basophils from six honeybee venom-allergic patients upregulated CD203c by a mean of 8.3 times. The study concluded that the CD203c-based flow assay could confirm the presence of venom-specific IgE antibody on basophils in 91% (20/22) of clinical history and skin test-positive venom-allergic patients. One false positive was observed among 13 skin test-negative healthy controls.

Diagnostic utility of basophil activation flow cytometric assays

The utility of basophil activation flow cytometric assays is limited by a number of technical concerns.⁵³ First, endotoxin free whole blood must be shipped within 24 hours to the laboratory, where it can be processed by skilled technologists. Second, the blood is pre-incubated with stimulation

buffer often containing IL3 that primes the basophils. It is unclear what effect IL-3 has on altering mediator release or CD63/CD203c upregulation, and thus false positive mediator release and/or biomarker surface expression are potential concerns.⁵³ Third, varying concentrations of crude allergen extract or recombinant allergen or anti-IgE need to be incubated with the cell preparation. Unfortunately, crude extracts can often be cytotoxic, and thus each stimulating allergen needs to be pre-qualified before use with cells. Fourth, criteria for defining positive assay results vary among stimulating allergen preparations from the same manufacturer owing to their variable potency. Fifth, there is a concern about false positive results related to platelet adherence on basophils in the CD63 assay. Possibly most important, when the performance characteristics were directly compared in clinical studies to puncture skin test results, the diagnostic sensitivity and specificity of the flow cytometric analysis of *in vitro* allergen-activated basophils is less than optimal. For these reasons, cell-based cytometry methods will most likely remain useful research techniques for the investigation of allergic disease, but have limited application to clinical diagnosis.

OTHER SERUM ANALYTES

Several other analytes can be measured in the diagnostic allergy laboratory to support the differential diagnosis of allergies, asthma or hypersensitivity pneumonitis, and to aid in the management of asthmatic patients. These include eosinophil cationic protein, human IgG-precipitating antibodies specific for antigens in organic dusts, and cotinine and aeroallergen quantification in environmental specimens (e.g., surface reservoir dust).

EOSINOPHIL CATIONIC PROTEIN (ECP)

ECP is a basic protein present in the granules of the eosinophil in different forms, with molecular weights ranging from 18.5 to 22 kDa. Elevated levels of ECP have been detected in the serum, sputum and nasal secretions of individuals undergoing a late-phase allergic reaction (usually 6–24 hours after exposure), when an eosinophil influx is predominant at the reactive site.⁵⁴ Levels of immunoreactive ECP detected in the serum of 100 healthy subjects ranged from 2.3 to 16 μ g/L (95% range) with a geometric mean of 6 μ g/L. ECP measurements have limited clinical utility as an analyte for monitoring patients with extrinsic asthma and other allergic diseases where eosinophils may play a role in tissue damage.

PRECIPITATING IgG ANTIBODIES (PRECIPITINS)

Hypersensitivity pneumonitis (HP), also known as extrinsic allergic alveolitis, is a hypersensitivity reaction to antigenic organic dusts (e.g. molds, bird droppings) involving the lung interstitium and terminal bronchioles⁵⁵ (Chapter 49). Hours after a heavy antigenic exposure an acute form of hypersensitivity pneumonitis can occur, with chills, fever, malaise, cough, and shortness of breath. Whereas histology of the lung lesions indicates a cell-mediated pathology, most patients with hypersensitivity pneumonitis have high serum levels of IgG antibody to the offending antigen. Despite its insensitivity, the double diffusion method (Ouchterlony) of measuring precipitating antibodies remains a means of confirming exposure but not necessarily the disease. In this assay, antigen (extract) and antibody (control or patient's serum)

Fig. 100.4 Distribution of *D. farinae* (*Der f. 1*) and *D. pteronyssinus* (*Der p. 1*) group 1 allergen levels as measured by monoclonal antibody based-enzyme immunoassay in respectively 647 and 741 fine dust specimens from across the USA. Results are reported in nanograms of allergen per gram of fine dust. The allergen levels are divided into quartiles, with the levels of demarcation noted by dashed lines. Proposed risk levels are also noted at 400, 2000 and 10 000 ng/g by solid lines. (Reproduced from Hamilton RG, Chapman MD, Platts-Mills TAE, Adkinson NF Jr. House dust aeroallergen measurements in clinical practice: A guide to allergen-free home and work environments. *Immunol Allergy Pract* 1992; 14: 9.)

diffuse towards each other in agarose gel, forming precipitin lines if high levels of antibody are present in serum. Precipitating antibodies or precipitins can be detected in the serum of nearly all ill patients, but also in the serum of as many as 50% of asymptomatic individuals who have been exposed to the relevant organic dusts.⁵⁵ Immunoassays for IgG antibody to the appropriate organic dust antigens may be less useful clinically because they are too sensitive. They typically detect IgG antibody in the sera of a higher number of nondiseased patients than do the immunodiffusion methods. Precipitin assays are currently available with specificities for the thermophilic actinomycetes (*M. faeni*, *T. vulgaris* and *T. candidus*), aspergillus (*A. fumigatus*, *A. niger*, *A. flavus*), pigeon serum, *Aureobasidium pullulans*, and fecal particles from parakeets and a variety of exotic household birds (Cockatiel, Amazon).

COTININE

One of the important triggers for asthma in children is passive or second-hand smoke exposure. Because parental self-reports of smoking status are not always reliable and custody cases often need definitive measures of passive smoke exposure, a number of biochemical markers (thiocyanate, nicotine, cotinine and carbon monoxide) in the plasma, saliva and urine have been used to validate claims of parental nonsmoking.⁵⁶ Analysis of

nicotine by gas chromatography or immunoassay is specific to tobacco, but its biological half-life is short. In contrast, cotinine, the major metabolite of nicotine, has a longer half-life and has become the marker of choice for monitoring passive smoke exposure. The rate of cotinine clearance in urine from nonsmokers (27.3 ± 1.9 h) is significantly longer than that of smokers (15.4 ± 1.2 h).⁵⁷ A diagnostic sensitivity of 97–99% and specificity 81–83% for cotinine in plasma, saliva and urine using 13.7, 14.2 and 49.7 ng/mL as their respective positive cut-off values⁵⁶ indicates that cotinine can serve as an effective marker of passive nicotine exposure regardless of the biological specimen that is collected.

ASSESSMENT OF ENVIRONMENTAL AEROALLERGENS

IgE-mediated diseases are currently managed using a combination of four approaches: pharmacotherapy of symptoms, allergen-specific immunotherapy, anti-IgE therapy and allergen avoidance. Of these, avoidance or the separation of allergen and patient is potentially the least expensive, best-tolerated and most effective approach for reducing allergy symptoms and minimizing increased sensitization. The level of aeroallergens in the indoor and outdoor environments can be highly relevant for the clinical management of allergic patients.

INDOOR ENVIRONMENTS

Allergen control in indoor home, school and work environments has become an important management technique for asthma. Of the known allergen specificities, aeroallergens produced by dust mites (*Dermatophagoides farinae*, *D. pteronyssinus*), fur-bearing pets (cats, dogs) and rodents (mice, rats), indoor insects (cockroach) and a limited number of common molds (*Penicillium*, *Aspergillus*, *Alternaria* and *Cladosporium*) are known to produce the majority of indoor allergic diseases.⁵⁸ A number of diagnostic allergy laboratories evaluate reservoir (surface) dust collected by allergic patients from defined areas of their homes, workplaces and schools. The extracts are then analyzed in a panel of monoclonal antibody-based immunoenzymetric assays to quantify indicator indoor aeroallergens: *Der f 1* and *Der p 1* (25 kDa allergens excreted into fecal particles by dust mites [*D. farinae*, *D. pteronyssinus*]), *Fel d 1* (35 kDa allergen excreted by the sweat glands of the domestic cat [*Felis domesticus*]), *Bla g 1/Bla g 2* (25–36 kDa allergens produced by the German cockroach [*Blattella germanica*]), *Mus m 1* (19 kDa allergen excreted into urine by the mouse [*Mus musculus*]) and *Rat n 1* (17 kDa allergen excreted in urine by the rat [*Rattus norvegicus*]). A viable mold spore analysis can also be performed on 5 mg of fine dust in a microbiological culture plate containing Sabouraud's dextrose agar.⁵⁸

Intra- and inter-laboratory variability of aeroallergen measurements has been assessed with a multicenter proficiency study conducted by the US Department of Housing and Urban Development.⁵⁹ In this study, aliquots of homogeneous batches of house dust and filtered dust extracts were provided to eight commercial, academic and municipal laboratories. The dust preparations were each analyzed for *Der p 1*, *Der f 1*, *Fel d 1*, *Can f 1*, *Bal g 1* and *Mus m 1* by enzyme immunoassays. Coefficients of variation on the estimated geometric means of analytical results ranged from 61% to 93%, with the dominant component of variability being variation between laboratories using different reagents. In spite of this variability, it was concluded that reasonable agreement was observed

CLINICAL PEARLS

INDOOR AEROALLERGEN ANALYSES

- >> Predominant indoor aeroallergens include dust mites, cockroaches, epidermal allergens (cat, dog, mouse, rat) and a limited number of molds.
- >> Quantitative analysis of house dust samples enables allergic subjects to assess the individual risk for symptoms and/or sensitization in a particular home and to monitor the effects of environmental control.

between the means of allergen levels across participating laboratories. The data provided confirmation that aeroallergen results from CLIA-88-licensed reference laboratories that use enzyme immunoassay procedures display a level of accuracy and precision that is acceptable for distinguishing environments with high aeroallergen levels (e.g. expected to trigger asthma in predisposed individuals) from those with lower levels considered to be safe.

Allergens that are measured in reservoir dust can be considered 'indicator' molecules because they allow the clinician and the patient to track the relative levels of associated allergen source(s) by room throughout a house, school or workplace. Figure 100.4 shows a representative distribution of *D. farinae* (*Der f*1) and *D. pteronyssinus* (*Der p*1) group 1 allergen levels as measured by enzyme immunoassay in respectively 647 and 741 fine dust specimens from across the USA. Levels of *Der p*1 and/or *Der f*1 allergen >2000 ng/g of fine dust have been associated with an increased risk of allergic symptoms in sensitized individuals, whereas levels >10 000 ng/g of fine dust have been associated with an increased risk of sensitization.⁶⁰ For cat, *Fel d*1 levels >8000 ng/g of fine dust have been proposed as a threshold for sensitization. Any cockroach allergen, mouse and rat allergen detected in an environment identifies an indoor area that places individuals allergic to cockroach, mouse or rat at risk for symptoms and sensitization. Finally, viable mold spore levels above 25 000 colonies/g of fine dust place the mold content in the environment above the 75th percentile for homes monitored across the USA. Where these proposed threshold levels are exceeded, the allergic individual is encouraged to take action to reduce the levels. A detailed discussion of strategies for doing this can be found elsewhere.⁶⁰ Repeat household dust allergen measurements following an intervention allows monitoring and documentation of allergen reduction.

OUTDOOR ENVIRONMENTS

In most major cities across the USA, aerobiology stations have been established to perform a daily evaluation of the outdoor air for pollen and mold spore levels. Daily information is often transmitted to local weather stations and newspapers for public use, or posted in allergists' offices for their patients to review. An aerobiology network has been established by the American Academy of Allergy, Asthma and Immunology to certify participating laboratories and monitor their performance. This network also collates and disseminates pollen and mold data across the nation throughout the allergy season.

Molecular methods

John W. Belmont

101

Molecular analysis of nucleic acids provides broad tools for the clinical laboratory. This chapter reviews the basic principles that underlie clinical molecular genetic testing, assesses representative methods that can be employed, and suggests a multidisciplinary approach for implementation in immunological disorders.

■ BASIC PRINCIPLES ■

GENOME STRUCTURE AND GENE EXPRESSION

The human genome is thought to contain 25 000–30 000 protein-coding genes distributed on 23 pairs of chromosomes (www.ncbi.nlm.nih.gov/entrez/). The total length of one copy of the genome is $\sim 3 \times 10^9$ nucleotide bases. The protein-coding segments (exons) are split by noncoding DNA sequences (introns). Some of the noncoding DNA contains regulatory elements that direct the expression of the genes, control chromatin conformation, act as origins for DNA replication, and produce the large-scale chromosome structure. About 40% of the total DNA is accounted for by families of repeated sequences. These repeat elements are generally silent, but may become involved in mutational mechanisms of deletion, duplication, and insertion. Each cell expresses only a subset of the entire gene repertoire. ‘Housekeeping’ genes are expressed in almost all tissues and cell types, where they perform basic metabolic and structural functions. Other genes are under very specific control and their expression is restricted to one or a few cell types. Differential gene expression specifies the unique functions of cells, e.g., globin in erythrocytes, immunoglobulin in B cells, and T-cell receptor in T cells. Genes that coordinate the expression of groups of tissue-specific genes primarily encode transcription factors that regulate the rate of mRNA transcription on their target genes. A few of these apparently act as ‘master’ genes during particular developmental processes or in specific cell lineages. Some of these master genes may be involved in leukemias and lymphomas. So far, immunodeficiency genes appear to be in the category of genes that involve either innate or adaptive immunity controlling cell growth, differentiation, effector functions, or apoptosis.¹

POLYMORPHIC VARIATION AND LINKAGE

A genetic map relates one gene to another based on how often they are inherited together. Within a specific region of the DNA or *locus* the maternal and paternal copies of the genome may be nonidentical and the variants are called *alleles*. Protein and nucleotide differences are called *polymorphisms* when they are frequent enough to be found in 1–5% of the general population. Variations in single nucleotides occur in $\sim 1/200$ bases when DNA sequencing is used to survey ~ 100 chromosomes.² Polymorphisms arise over time in a group of individuals because of mutations in the DNA. Some polymorphisms involve simple sequence repeats so that there is variation in the number of repeat units. These are called short tandem repeats (STR) and form the basis of the widely applied genetic marker maps that until recently played an important role in human linkage mapping. In contrast to STRs, the most common polymorphisms involve a change in a single nucleotide position. Large databases of single nucleotide polymorphisms (SNPs, pronounced ‘snips’) have been accumulated (<http://www.ncbi.nlm.nih.gov/SNP/>). It is thought that there could be $\sim 15\text{--}20 \times 10^6$ SNPs with minor allele frequency $>5\%$ available across the human genome. Many STR and SNP polymorphisms are found in noncoding DNA, but functionally significant polymorphisms also occur in protein-coding sequences and in regulatory noncoding DNA sequences, and these may play a large role in common human diseases.

The composition of alleles within genetic loci in an individual is called the *genotype*. The individual’s genotype interacts with the environment both in development and in maturity to create the *phenotype*. Some components of the phenotype, such as skin rash, can be relatively simple, whereas other phenotypes may be based on complex laboratory evaluation (e.g., in T-cell proliferation). A key distinction should be drawn between discrete traits and those that are represented by a quantitative continuum. Many laboratory values, which are essentially quantitative, can be reduced to discrete traits by assigning them to ‘normal’ or ‘abnormal’ status. Polymorphisms account for some of the variation that is observed at the phenotype level between healthy individuals and between populations, and the cumulative percentage of the variation explained by genetic variation is called the *heritability*. There is a general correlation of

KEY CONCEPTS

HUMAN GENOMICS

- >> The human genome encompasses approximately 25 000 protein-coding genes, but each cell expresses only a subset of those genes.
- >> Genetic and physical maps of the genome are essential to molecular diagnosis of immune system diseases.
- >> Genetic maps depend on the co-inheritance of DNA segments – linkage – to derive gene order on individual chromosomes.
- >> Physical maps of the genome describe the exact gene locations on a chromosome. The genome DNA sequence is the finest-scale physical map of the genome.

allele frequency with the age of polymorphism, i.e., the older the polymorphism the greater the allele frequency and the greater the likelihood that it will be observed in all ethnic groups. Indeed, the more common allele is most often ancestral within the whole human population, in the sense that it is generally the base observed at the homologous position in chimpanzee and other primates. Polymorphisms are the key to tracking the inheritance of whole segments of adjacent DNA and are thus used to follow disease genes in families.

During the formation of the haploid germ cells – ova and sperm – one member (homolog) of each parental chromosome pair is segregated to one of two daughter nuclei (first meiotic division; Fig. 101.1). Because each chromosome is essentially independent of the others, genes on different chromosomes are independently segregated and unlinked. If any position along a pair of chromosomes differs between the two, then the variants are called *alleles*. The arrangement of alleles along a chromosome is called the *haplotype*. For each autosome there are literally two chromosome-length haplotypes per individual. During meiosis, *recombination* between homologous chromosomes leads to intermixing of the two parental genomes. Each chromosome may cross over an average of two to three segments per meiosis. When loci are close together on the same chromosome there is less chance for recombination between them and the *phase* in which they start is more likely to be unaltered through meiosis (Fig. 101.2). If the loci are far apart on a chromosome then it is likely that at least one crossover will come between them during meiosis. Because the physical distance between two loci determines whether they will be inherited as a block during meiosis, a statistical relationship can be developed that indicates how likely two segments are to be co-inherited. *Linkage* between two loci can be quantified as the recombination fraction θ . Linkage is present if the fraction of recombination is <0.5 (i.e., a 50:50 chance of co-inheritance). θ is often expressed in centimorgans (cM), so that if two loci are 1 cM apart then there is a 1% chance of recombination at meiosis. 1 cM is on average equivalent to approximately 1 million base pairs (bp) of DNA. However, the recombination rate between two loci can be affected by factors other than physical distance, e.g., the presence of repeat sequences that may favor recombination or proximity to the centromere that may suppress recombination. The same processes of haplotype formation and shuffling of haplotype segments by recombination along chromosomes shapes the correlations between markers in the population as whole.

Genes can be mapped in relation to one another by a linkage map. Genes that are physically close can be shown to be predominantly co-inherited. The usual way to express this relationship within a family linkage study is with the LOD score – log of the odds of linkage – which compares the chance of two gene segments being co-inherited with the situation in which they are unlinked. Conventionally, if the LOD is >3.0 (or 1000:1 in favor of the genes being linked) the results are considered significant. One major achievement of the human genome project has been to develop linkage maps for humans. The use of marker loci that show a high degree of polymorphism is particularly useful for this. Whereas linkage in this sense is best observed in families, the same phenomenon persists at a very fine scale in the population. The correlation of alleles among markers that are very close to each other in the genome is called *linkage disequilibrium* (LD). LD occurs because the mutation that creates a polymorphism occurs on a single chromosome. Then various demographic factors (drift, migration, and selection) cause the variant to become more frequent over time. The arrangement of alleles, however, is broken up by recombination over time as well. Hence, only markers that are relatively close to each other continue to have significant LD. A large international project (HapMap) has recently created a dense map of SNP markers allowing a view of LD in several reference populations.

Linkage mapping played a large role in the identification of the X-linked immunodeficiency genes (Chapters 21, 34–36). Linkage has been much less useful for the identification of autosomal recessive genes responsible for rare immunodeficiencies because average families are not large enough to be used by themselves. Another difficulty is that similar diseases can be caused by mutation in more than one gene locus (locus heterogeneity). Extremely dense LD maps have recently become available,² and these are expected to facilitate the identification of many more disease genes using powerful new study designs in large populations.

PHYSICAL MAPS AND MOLECULAR CYTOGENETICS

Genetic or linkage maps can be contrasted with the physical gene map. Physical maps are different from the genetic map in that they describe how genes are arranged in the DNA on a scale as large as a whole chromosome and as fine as a single nucleotide. At the coarsest level of the physical map, genes are placed in chromosome segments corresponding to the Giemsa stain banding pattern of metaphase chromosomes. This physical map is encompassed in a set of bacterial artificial chromosome (BAC) clones that have DNA inserts of approximately 90 000–250 000 nucleotides that provided the scaffold for the public genome sequencing project. BAC clones now provide extremely useful reagents for both research and clinical purposes.

A very important way to localize genes after they have been cloned is to hybridize them directly to a chromosome spread. The technique, called fluorescence in situ hybridization (FISH), allows the detection of signals from the chromosome spread to directly localize genes.³ FISH is used for cytogenetic examination of tumors, leukemias, and lymphomas. In the DiGeorge syndrome, characteristic deletions of chromosomes 22q11 or 10p13 cannot be detected by chromosome analysis only (Chapter 35). FISH is now gradually being replaced by microarray comparative genome hybridization (CGH), which examines many hundreds of chromosomal positions simultaneously on a printed array of BAC clones.⁴ Newer high-density oligonucleotide arrays promise whole genome resolution of <100 Kb. These methods are detailed below.

Fig. 101.1 Independent segregation of chromosomes during meiosis. The diploid adult cells give rise to all combinations of parental chromosomes. Genes on different chromosomes are unlinked. Detection of this phenomenon depends on distinguishing allelic polymorphisms, i.e., A or a, B or b.

Fig. 101.2 Recombination.

MUTATION

Mutations may involve small or large deletions, insertions, inversions, or duplications. Some mutations may have no measurable or functionally significant phenotypic effect. They become one of the huge pool of neutral polymorphisms in the genome. Single base substitutions in a

triplet amino acid codon often disturb the normal function of proteins. These are described as missense (i.e. causing an amino acid substitution) or nonsense (i.e. terminating translation). Mutations affecting regulatory or splice signal sequences in RNA can also be deleterious. Primary mechanisms of mutation are misincorporation of nucleotides and faulty repair of chemically damaged nucleotides (e.g., 8-oxodG) during DNA replication by DNA polymerases.^{5,6} Another important mechanism underlying single base or 'point' mutations occurs at CpG dinucleotides.⁷ The cytosine is often methylated, and chemical deamination of the methylated cytosine gives the base thymidine. At the next round of replication the CG may be changed to TG or CA, depending on which DNA strand was altered. CG is found in the amino acid codons of Arg, Ser, Pro, Thr, and Ala. These amino acids are frequently involved in coding sequence mutations. Small insertion and deletion (indel) mutations are also very common. Indels occurring in protein coding sequence are frequently deleterious as they may cause frameshifts (changing the reading frame, usually leading to translation termination within a few codons). They result from strand slippage in repetitive sequence and misaligned intermediates during DNA synthesis.⁸ Finally, an entirely different and novel mechanism for mutation is expansion of unstable triplet repeat segments.⁹ So far, no disorder that affects the immune system has been associated with this mechanism. As outlined below, mutation screening will have a continuing and expanding role in clinical molecular testing.

Heritable mutations may arise in either the male or the female germline, but the gender-related frequency is influenced by the mutational mechanism. Chromosomal nondisjunction, for example, occurs predominantly during female meiosis and has a strong maternal age effect.¹⁰ The fact that spermatogonial proliferation occurs throughout life and involves many more cell replications than oogenesis increases the single base mutation frequency in the paternal germline. A 20-fold risk for point mutations and a 11-fold risk of mutations at CpG dinucleotides occurring in the male germline has been observed in the factor IX gene.¹¹

Clinicians must cope with both locus and allele *heterogeneity*. Locus heterogeneity means that the same or a similar phenotype results from mutation in one of several different genes. For example, severe combined immunodeficiency (SCID) may result from mutation in the adenosine deaminase, interleukin-2 receptor γ -chain genes, etc. Allelic heterogeneity, on the other hand, means that the disease is caused by different mutations in the same gene. In X-linked disorders allelic heterogeneity is typically high because affected individuals have reduced reproduction (negative evolutionary selection) and most mutations are lost in the population after a few generations. At autosomal loci some mutations have reached appreciable frequency due to demographic processes, e.g., founder effect. In the heterozygous state, recessive mutations may be weakly deleterious, neutral, or actually confer a small advantage. In cystic fibrosis¹² and Tay-Sachs disease,¹³ for example, a few mutations account for a large percentage of the abnormal alleles. The heterozygote frequency in those disorders may be increased by relative resistance to *Salmonella*¹⁴ and tuberculosis,¹⁵ respectively. Because the mutant alleles are common, it is possible to test affected individuals and potential carriers directly for those mutations. Certain important HLA alleles that increase the risk of autoimmune disease may owe their prevalence to either founder effects or selective advantage. In contrast, none of the immune deficiencies, with the exception of SCID due to Artemis/DCLRE1C mutation seen in Native Americans of the Southwest (OMIM 602450),¹⁶ result from common mutations that would permit efficient screening. In the autosomal recessive immune deficiencies most patients have two different mutations (*compound heterozygosity*) at the disease locus unless there is parental consanguinity.

X CHROMOSOME INACTIVATION

Disturbances in the pattern of X inactivation are interesting phenomena in women who are carriers of X-linked immune deficiencies. Measurement of X chromosome activity in the blood cells of normal women shows that on average the contribution of maternal and paternal X chromosomes is approximately 50:50. Extreme skewing of X inactivation often results from abnormal proliferation of blood cells. X inactivation analysis can be used to demonstrate clonal growth of premalignant (e.g. myelodysplasia) and malignant cells. In a female carrying mutations at the X-linked severe combined immune deficiency (XSCID, OMIM 300400), agammaglobulinemia (XLA, OMIM 300300), or Wiskott-Aldrich (WAS, OMIM 301000) loci, cell competition and compensation mechanisms lead to a reduced contribution of cells expressing the mutant allele among affected cells.¹⁷ In XLA, the B-cell lineage shows selective use of the nonmutant active X. In XSCID, skewing of X inactivation is observed in B cells, T cells and NK cells. In WAS, some degree of skewing of X inactivation results from defective hematopoietic stem cell activity.¹⁸ Historically, skewed X inactivation was very helpful in linkage mapping of these conditions. As a clinical test, X inactivation now has

KEY CONCEPTS

MUTATION

- >> Mutation can occur by deletion, insertion, or duplication of short or long DNA segments.
- >> Single-base mutations can be caused by replication errors or by chemical deamination of methylcytosine.
- >> Single-base mutations can affect protein coding sequence, regulatory sequences, or the RNA splice signals within a gene.
- >> The parental origin of mutations (maternal or paternal) affects which mutational mechanisms were most likely responsible.
- >> A disease can be caused by mutations in several alternative genes (locus heterogeneity).
- >> Most primary immune deficiency disease occurs because of different kinds of mutations in particular genes (allelic heterogeneity).

reduced importance compared to direct mutation analyses. There may be some role for X inactivation assays to clarify carrier status when mutation analysis is incomplete or unsuccessful.

DESCRIPTION AND PRINCIPLES OF DNA DIAGNOSTIC TECHNIQUES

The overriding theme of all DNA diagnostic techniques is the specific detection of one or a few segments of DNA in the complex mixture of sequences encompassing the genome. There are four key techniques in gene diagnosis: restriction enzyme digestion, DNA:DNA hybridization, polymerase chain reaction, and DNA sequencing. In addition to these, one should now add computer-based data management or *bioinformatics* as a necessary diagnostic laboratory discipline. A new generation of microarray techniques is emerging that combines these methods into highly parallel assays on ‘gene chips.’

SOUTHERN AND NORTHERN BLOTTING

Southern blot analysis was one of the first techniques to find wide clinical application. In a Southern blot, genomic DNA is digested with a restriction enzyme that cuts at a short specific (4–8 bp) segment of DNA (Fig. 101.3). The very long pieces of chromosomal DNA are cleaved into much smaller units that range from a few hundred to tens of thousands of base pairs. The digested genomic DNA is separated on the basis of fragment length on an agarose gel. Because genomic DNA is very complex the digested DNA looks like a smear, but because cleavage by the restriction enzyme is sequence specific, the pattern of digestion is very reproducible. The separated DNA is transferred and fixed to a filter membrane and then incubated with a labeled and denatured DNA probe. The probe is most commonly labeled with ³²P, but nonradioactive probes, particularly those using chemiluminescence technology, rival the sensitivity achieved with radiolabeling.¹⁹ When the probe DNA finds a complementary sequence on the filter, it

Fig. 101.3 Southern and Northern blotting. Probe DNA is usually produced by incorporation of ^{32}P -dCTP into newly synthesized DNA. See text for further explanation.

hybridizes. The hybrids are stable to washing, whereas nonspecifically bound probe is washed away. The filter is then analyzed by autoradiography or a phosphor imaging device. Northern analysis is very similar, but instead of using enzyme-digested genomic DNA one probes RNA. Whole RNA or affinity-purified polyadenylated mRNA can be used. The RNA is separated under denaturing conditions to avoid the self-hybridization (secondary structure) that might affect migration in the gel.

Southern blotting continues to be useful in analysis of the immunoglobulin and T-cell receptor loci in leukemias and lymphomas.²⁰ Its main use is that it can scan many thousands of base pairs of DNA. It is likely to remain a preferred method in clinical applications in which the complexity or primary sequence of the locus makes DNA amplification difficult.

X-CHROMOSOME INACTIVATION

To measure X inactivation one must distinguish the two chromosomes and determine whether the products of those chromosomes are equally active. Various assays have been used, but the human androgen receptor locus (HAR) is most widely applied.²¹ HAR contains a highly polymorphic trinucleotide (heterozygosity 0.9) repeat in the first exon. This repeat is within ~100 bp of two Hpa II restriction enzyme sites that are methylated on the inactive X chromosome but unmethylated on the active X. In the normal situation, some DNA from both alleles is active and some is inactive. Therefore, the PCR products from Hpa II-cut DNA reflect the presence of both allele templates. If one allele is exclusively active its potential to be a template is destroyed by Hpa II digestion and it will disappear from the PCR products. X inactivation studies have a limited role in carrier detection in XLA, XSCID, and WAS pedigrees

and nuclear families, but may occasionally be helpful if direct mutation detection is unsuccessful.

FLUORESCENCE IN SITU HYBRIDIZATION (FISH)

FISH provides a significant advance over older techniques that used radioactive labels for probing genes directly on chromosome spreads.²² In its simplest form a cloned gene segment is labeled with biotin- or digoxigenin-tagged nucleotides, but more complex labeling strategies are now commonly used.²³ These are detected with secondary antibodies and high-sensitivity immunofluorescence techniques. The probe is hybridized to chromosomes from cells that are prepared to allow visualization of early metaphase (condensed) chromosomes. A locus appears as two pairs of dots corresponding to the sister chromatids from the two chromosomal homologs. Cells that are in interphase (when the DNA is largely unfolded in the nucleus) can also be probed. In the interphase cell, two single signals are observed corresponding to the two chromosomes. FISH plays an important role in detecting known common rearrangements, such as the deletions observed in DiGeorge syndrome or the translocation of *BCR-ABL* in chronic myelogenous leukemia. Spectral karyotyping (SKY),^{23,24} in which each chromosome is labeled with a differentiating pattern of fluorescent dyes, has also been used extensively in the diagnostic evaluation of neoplasias. Comparative genome hybridization (CGH)⁴ uses normal and potentially abnormal DNA, e.g., from a tumor, to prepare probes that are differentially labeled with fluorophores. The ratio of fluorescence signal from each probe source is then evaluated on normal chromosomes, and areas of loss or amplification are detected by segmental variation in the ratio. This method has proved to be a stepping stone to microarray analyses that dramatically refine the resolution of the analysis.²⁵

PCR AND OTHER NUCLEIC ACIDS
AMPLIFICATION TECHNIQUES

DNA amplification using the polymerase chain reaction (PCR) was a watershed advance in the detection of specific nucleic acid sequences.²⁶ PCR depends on the ability of two short synthetic oligonucleotides to find the DNA that closely matches each one (Fig. 101.4). A thermostable enzyme is added that can synthesize new DNA using each oligonucleotide as a primer, resulting in a doubling of the segment between the primers. The presence of the complementary oligonucleotide allows a second strand of complementary DNA to be synthesized. This constitutes one cycle of PCR. When this cycle is repeated, the segment of DNA in between the oligonucleotides is geometrically increased. RNA can also be amplified by first synthesizing complementary DNA (cDNA) using viral reverse transcriptase (RT-PCR). The amount of product then becomes great enough to detect, either by hybridization or by direct

visualization on an ethidium bromide-stained gel. PCR can theoretically detect a single molecule of DNA or RNA. Thus, small cell or tissue samples can be analyzed very rapidly. One variation is to label one of the oligonucleotides, either with a radioactive molecule such as ³²P or with a fluorescent tag. PCR provides the starting point for linkage assays, mutation analysis, and DNA sequencing. RT-PCR is finding use in the quantification of mRNA from blood cells, e.g. in measuring cytokine transcription from activated T and B cells. Using specially designed instrumentation it has become possible to monitor and quantify the synthesis of DNA at each cycle of amplification in a PCR. These methods are called ‘real-time’ PCR and they provide sensitive assays for quantification of DNA and RNA, e.g., in assessment of HIV load.²⁷ The real-time PCR instrument detects fluorescent reporters such as SYBR Green (fluoresces when bound to double-stranded DNA). TaqMan and molecular beacons are related techniques in which oligonucleotide probes are dual-labeled with a fluorescent reporter and a

Fig. 101.4 Polymerase chain reaction. (A) Primers that hybridize to the target sequence are used to initiate multiple cycles of synthesis, melting, annealing, and synthesis. In practice, the potential geometric increase in DNA tapers off as reaction components become limiting. (B) Primers. PCR flanking a triplet (AAT)_n repeat segment at DXS101 allows the detection of allelic differences. This polymorphism is tightly linked to the XLA locus and can be used to track inheritance of the disease in a family.

quencher moiety. Molecular beacons are oligonucleotides that can form stem-loops in which the loop can hybridize to a specific target DNA sequence. A fluorescent dye is covalently linked to one end of the stem and the quencher is attached to other end. The probe anneals to PCR products, causing the arm sequences to separate such that the amount of fluorescence is proportional to the increasing amount of target DNA in the reaction at each cycle. The TaqMan reaction is described in the section on detection of known mutations, but the same technique is also useful for quantification of specific nucleic acids.

There are a variety of other amplification techniques with application in clinical diagnostic laboratories. PCR uses cycles of denaturation and annealing of double-stranded DNA to achieve amplification, but there are also isothermal (processes occur at a single temperature) methods for nucleic acid amplification. Nucleic acid sequence-based amplification (NASBA) utilizes reverse transcriptase, RNase H and T7 polymerase in an isothermal process that produces single-stranded RNA as the amplification product.²⁸ Transcription-mediated amplification (TMA) amplifies RNA using reverse transcriptase (RT) and RNA polymerase.²⁹ The RT makes double-stranded DNA copies that are used by the RNA polymerase to synthesize multiple copies of the single-stranded RNA. The branched-DNA assay uses the accumulation of branched enzyme-conjugated DNA probes on target DNA trapped on a solid phase.³⁰ Pre-amplifier and amplifier molecules are then hybridized to the captured target. Labeled oligonucleotides hybridize to the branched DNA complex and are then detected using a chemiluminescent enzyme substrate.

Segments of DNA that are variable in length between individuals can be readily detected by PCR. A class of polymorphism that is easily distinguished by PCR is called a microsatellite. These short tandem repeat polymorphisms (STRP) are principally dinucleotide, trinucleotide, and tetranucleotide elements that vary in the number of repeat subunits between individuals.³¹ STRs have much higher mutation rates than

single nucleotide positions (~1000 times greater).³² This instability creates extensive families of alleles. In general, the longer the uninterrupted repeat segments, the greater the chance that the element will be polymorphic. At many of these loci the heterozygosity is 70–90%. Polymorphic short tandem repeats are distributed in the genome approximately every 40 000 bases. It has been possible to identify them either close to or within most genes of medical interest. Their high degree of heterozygosity and the ease of the assay have made microsatellites an important tool for disease gene mapping and positional cloning. Improved technology for SNP detection has largely displaced STRPs for research.³³

DNA SEQUENCING

The direct determination of a DNA sequence is fundamental to mutation identification (Fig. 101.5). The most commonly used method (called Sanger sequencing) depends on termination of DNA synthesis by chemically modified nucleotides (dideoxy-NTPs). A single-stranded DNA template is hybridized to a primer that can recognize a short known segment of DNA. The single-stranded DNA is obtained from bacterial plasmid/phage vectors, or may be produced by DNA amplification. The primer acts as a starting point for DNA synthesis by a DNA polymerase that is added to the reaction. Four separate reactions are set up, each 'spiked' with one of the four possible dideoxynucleotides (ddATP, ddTTP, ddCTP, or ddGTP). As synthesis proceeds, some of the strands incorporate a dideoxynucleotide and no further extension can take place. In each reaction a family of molecules is synthesized whose unit lengths are determined by whether the reaction had been terminated by incorporation of a specific dideoxynucleotide at a given position. Either the primer or the nucleotides may be labeled. Automated instrumentation for DNA sequencing using laser scanning of fluorophore-labeled reactions has largely replaced other labeling schemes. By using four different fluorescent labels the reaction products

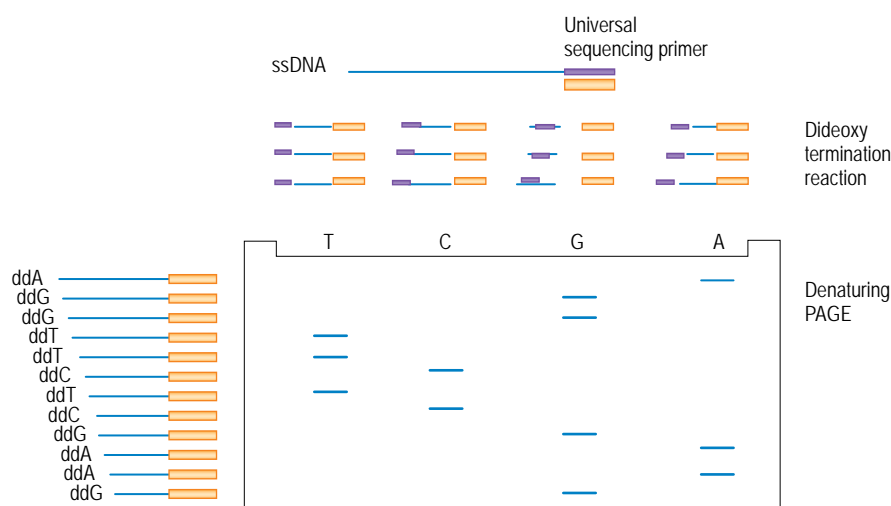

Fig. 101.5 DNA sequencing by dideoxy-NTP chain termination. Copying of the DNA by the polymerase is terminated at specific positions when a ddNTP is incorporated. The ddNTP is added mixed with dNTPs so that, in each reaction, only some new strands terminate whereas others continue through to the next complementary nucleotide. The sequencing products can be visualized by autoradiography or by laser scanning in an automated sequencer.

can be analyzed together. Two classes of chemistry are popular: 'dye primer', in which the primers of each reaction are tagged with different fluorophores, and 'dye terminator', in which the dideoxynucleotides are themselves labeled with fluorophores. Advances in both dye primer³⁴ and dye terminator chemistry³⁵ greatly improved the accuracy of quantification and base calling. The original instrumentation for automated fluorescent sequencing used large polyacrylamide gels, but the most recent generation of instruments exploits large renewable capillary electrophoresis arrays. These instruments (exemplified by the AB 3730xl) were crucial to completion of the reference human genome sequence.

Fig. 101.6 Array-based DNA sequencing. **(A)** Pyrosequencing carried out in high-density picoliter reactors. In this method single molecules of DNA are hybridized to tagged beads and PCR is carried out in an emulsion. The beads bearing the resulting amplified products are distributed into microfabricated wells in which pyrosequencing reactions can be cycled. The release of PPI with each cycle is monitored by an enzyme-linked production of ATP, which in turn cause luciferase to emit light. An instrument that integrates these steps is produced by 454 Life Sciences. **(B)** Cyclic reversible termination (CRT). This is a method being explored at a research level in which fluorescent labeled terminator nucleotides are added and then imaged. After deprotection, another cycle of addition and imaging can take place.

New technologies that promise to dramatically increase the throughput and reduce the cost of DNA sequencing are being intensely investigated.³⁶ Unlike Sanger sequencing, which produces sequence data by controlled termination of the polymerase, the new techniques derive the sequence as nucleotides are sequentially added by the polymerase. Two of these chemistries have now been developed into early-stage high-throughput sequencing instruments (Fig. 101.6). The first of these uses pyrosequencing chemistry. Pyrosequencing works by detecting the release of pyrophosphate as nucleotides are added to a DNA primer hybridized to template DNA.³⁷ DNA polymerase can extend the primer when there is a complementary dNTP available, but stops when only a noncomplementary base is present. DNA synthesis is reinitiated following the addition of the next complementary dNTP. Pyrophosphate is released as the base is added to the growing DNA chain and detected by enzyme amplification. The sequencing instrument controls the order of dNTP addition to the reaction. The order of base addition coupled to the light emission is then decoded as the sequence. The 454 Life Sciences Corporation instrument exploits pyrosequencing on an array of about 300 000 microscopic (40 μ m) wells (Fig. 101.6A). The wells each contain a single sepharose bead on which are coupled the reaction products of a single molecule of template DNA, which itself has been amplified in an oil-and-water emulsion.³⁸ An advantage of clonal amplification is that it deals neatly with the problem of heterozygosity. The pyrosequencing reaction is monitored in a fiberoptic system. Read lengths of about 100 nucleotides are feasible. Another general method of sequencing is called cyclic reversible termination (CRT). CRT uses cycles of base addition, imaging, and deprotection to follow the sequence of DNA synthesized on an unknown template. Fluorescence CRT exploits fluorescent-dye labeled reversible terminator nucleotides (Fig. 101.6B). These specialized nucleotides have a protecting group that terminates DNA synthesis. The fluorescent label can then be imaged. Catalytic removal of the protecting group then allows another cycle of base addition and imaging. 3'-O-allyl dNTPs were recently reported to have suitable properties for DNA sequencing.³⁹ An instrument and reagents that exploit this method is being introduced by Solexa Inc. Their method combines this chemistry with in situ

KEY CONCEPTS

MOLECULAR METHODS

- >> Most DNA diagnostics rely on DNA hybridization restriction enzyme digestion, polymerase chain reaction (PCR), and/or DNA sequencing.
- >> Southern blots directly detect a DNA segment within the complex mixture of the entire genome.
- >> PCR allows an exponential amplification of a DNA segment from the genome, allowing multiple analytical procedures on the single pure sequence.
- >> New high-throughput genotyping and sequencing methods which use microarrays are beginning to emerge as practical alternatives to older single analysis approaches.
- >> Bioinformatics is an emerging discipline relevant to molecular diagnosis. Integration of bioinformatics techniques plays a necessary role in data acquisition and interpretation.

amplification of large numbers of single DNA molecules. This is called bridge amplification, because the both PCR primers are covalently attached to a solid phase and the amplification products accumulate on that surface. The potential is for simultaneous sequence analysis of >1 M molecules per assay. The general goal of a '\$1,000 genome' articulated by the National Human Genome Research Institute no longer seems like a pipedream. Although there will be some lag in clinical application, it is highly likely that mutation scanning of large numbers of genes, or even complete genome sequencing, will be feasible in the near future.

MUTATION SCANNING AND DETECTION

Individual mutation analysis has become the principal focus of diagnostic molecular biology. Improvements are continuing to allow for faster, less expensive, and more extensive screening of individual patient samples. Ideally, mutation analysis begins with some knowledge of the mutational spectrum at a particular locus. Some mutations recur commonly because of the large-scale genomic structure around a disease gene. Examples of this are the common inversions of the factor VIII locus⁴⁰ and the common deletions seen in the spinal muscular atrophy locus.⁴¹ Common mutations, such as $\Delta F508$ in cystic fibrosis⁴² and N370S in Gaucher's disease,⁴³ illustrate simple mutations that have high allele frequency owing to population demographic effects.^{44, 45} Certain nucleotide positions may have a greater rate of mutation, and these may explain recurrent – albeit rare – mutations in some genes. Beyond these common mutations, the mutational spectrum at these loci and most others is very diverse. Mutations 'private' to particular families are routinely observed. Clinical mutation analysis must therefore deal with known common mutations, identify family-specific mutations, and flexibly genotype at-risk individuals once a familial mutation is found.

DETECTION OF AN UNKNOWN MUTATION

Methods for the detection of single-base substitutions in DNA are increasingly important in the diagnostic laboratory.⁴⁶ Although cDNA synthesized from mRNA can be used, analysis of genomic DNA is far more common, and this discussion is restricted to that problem. The first step is the designing of PCR primer sets that will allow amplification of each exon. The availability of the reference human genome sequence makes determination of gene structure and amplicon design for genomic DNA straightforward, although there is often considerable design and redesign before reliable working primer sets are achieved. Any mutation that directly affects amplification, such as deletion or mutation in the amplicon sequence itself, can produce misleading results. It is always desirable to have parental specimens available to serve as a reference for proving biallelic inheritance in the affected offspring.

Many different methods for mutation screening have been described (see the second edition of this book for a more extensive discussion of these techniques). Mutation site cleavage, detection of conformation alteration or heteroduplexes by denaturing electrophoresis or chromatography; and direct mutation site detection by DNA sequencing are several of the major classes of technique. Cleavage methods have not been widely applied in diagnostic laboratories, and so this discussion will focus on heteroduplex detection and sequencing. In single-strand conformational polymorphism (SSCP),⁴⁷ the amplified DNA PCR product is

denatured and then separated on a native acrylamide gel. Single-stranded DNA assumes some secondary structure due to internal base pairing, and each strand has a unique mobility based on size and shape. Under appropriate conditions, using short segments of DNA, single-base differences can be seen to alter the mobility in the acrylamide gel of one or both of the complementary DNA strands. Using 150–200 nucleotide-long PCR products, 70–95% of mutations can be detected with this method. A similar method is called heteroduplex analysis or conformation-sensitive gel electrophoresis (CSGE).⁴⁸ This method depends on the hybridization of complementary strands of mutant and normal (wild-type) alleles. This creates a mixture of heteroduplexes and homoduplexes with three resulting types of DNA hybrids: mutant/mutant, normal/normal, and the heterodimer that contains one mutant and one normal DNA strand. The mismatch configuration of this heterodimer means that it tends to migrate slightly differently in an agarose or acrylamide gel, and can thus be detected. Denaturing high-performance liquid chromatography⁴⁹ (DHPLC) is an efficient approach to semi-automated heteroduplex screening. It incorporates rapid and robust separation and detection technologies for heteroduplex detection (Fig. 101.7). This method directly detects single-nucleotide and insertion/deletion variation in crude PCR products. DHPLC uses a polystyrene–divinylbenzene copolymer matrix in a temperature-controlled column chromatography format. A linear gradient of acetonitrile at regulated temperatures allows separation of DNA from the column matrix based on fragment size and the presence of unstable heteroduplex structures. Under partially denaturing temperatures, the heteroduplexes elute from the column earlier than the homoduplexes because of their reduced melting temperature. Optimization involving more than three temperatures is not usually required because mutations are detectable over a broad range of column temperatures. An individual bearing compound heterozygous mutations at an autosomal locus will produce both heteroduplex and homoduplex PCR products, and these can be detected with high sensitivity in a

Fig. 101.7 Denaturing high-performance liquid chromatography (DHPLC). DNA heteroduplexes are separated from homoduplexes by their characteristic melting profile in a temperature-controlled acetonitrile gradient.

DHPLC system. An individual bearing a homozygous mutation at an autosomal locus or a hemizygous mutation at an X-linked locus will produce only homoduplexes. Depending on the nature of the mutation, the mutant homoduplexes may not be reliably distinguished from wild-type sequence based only on their elution profile on the column. Intentional introduction of wild-type DNA or PCR products as a secondary procedure can then be employed.

DETECTION OF A KNOWN MUTATION

Once a mutation has been identified in a patient, the entire family can be tested. One of the simplest methods is called oligonucleotide ligation assay (OLA).⁵⁰ In this procedure, pairs of specific oligonucleotides are designed to match exactly the wild-type and variant sequences. After a denaturing step, the temperature is reduced to one at which the oligos can hybridize with the single-strand template. Thermal-stable ligase is used to ligate the two oligos and the cycle is repeated. One popular method is to capture the ligated oligos in an ELISA so that the ligated products can be detected by conventional antibody and enzyme processes and quantified in a standard 96-well format plate reader. Amplification refractory mutation system (ARMS, Fig. 101.8A) and allele-specific primer extension (ASPE) are related techniques in which specific primer oligonucleotides are designed for each allele or mutation to be detected.⁵¹ Oligos with a perfect match will not allow either PCR or primer extension reactions. ASPE has been developed into an FDA-approved clinical test that achieves multiplexing by incorporating a tag address system with detection of fluorescent beads (Luminex; Fig. 101.8B). ‘Molecular beacons’ are specialized oligonucleotides that contain a fluorophore and a fluorescence-quencher group at opposite ends of the molecule⁵² (Fig. 101.9A). The probe oligos are designed to form a stem structure with an intervening loop that is complementary to the target sequence. In solution, the molecular beacon assumes a hairpin structure in which the fluorescence emission is quenched. In the presence of a perfectly matched target, the molecular beacon unfolds, placing the fluorophore and quencher far enough apart so that the fluorophore is no longer quenched. Fluorescence emission increases during PCR amplification. To determine whether a known mutation is present, specific probe oligos are designed to be exact matches for the wild-type and mutant DNA sequences. Different fluorophores with minimally overlapping emission spectra are used for each probe oligo, and their differential hybridization is monitored at each cycle of amplification. Specialized instrumentation is used to monitor single reactions or reactions in a 96-well format during the PCR amplification process. Another technique, the TaqMan reaction⁵³ (Fig. 101.9B), uses the same kind of instrumentation to monitor the PCR reaction in real time, but employs a slightly different approach to allele recognition. In the TaqMan method, the fluorophore is attached to the 5' end of the probe and a quencher to the 3' end. The 3' end is modified so that it cannot be used as a primer for polymerase extension. In its native state this oligo is quenched. The TaqMan probe hybridizes to the target sequence as it is produced in the PCR reaction. As the Taq polymerase extends on the template, the probe oligo is displaced and the 5' end becomes a substrate for the exonuclease activity of the polymerase. Cleavage of the 5' base from the oligo releases the fluorophore and the quenching is relieved. The increase in fluorescence emission as the PCR reaction proceeds is monitored in the instrument. Allele-specific genotyping for mutant or wild-type forms is again accomplished by designing specific probe oligos for each sequence.

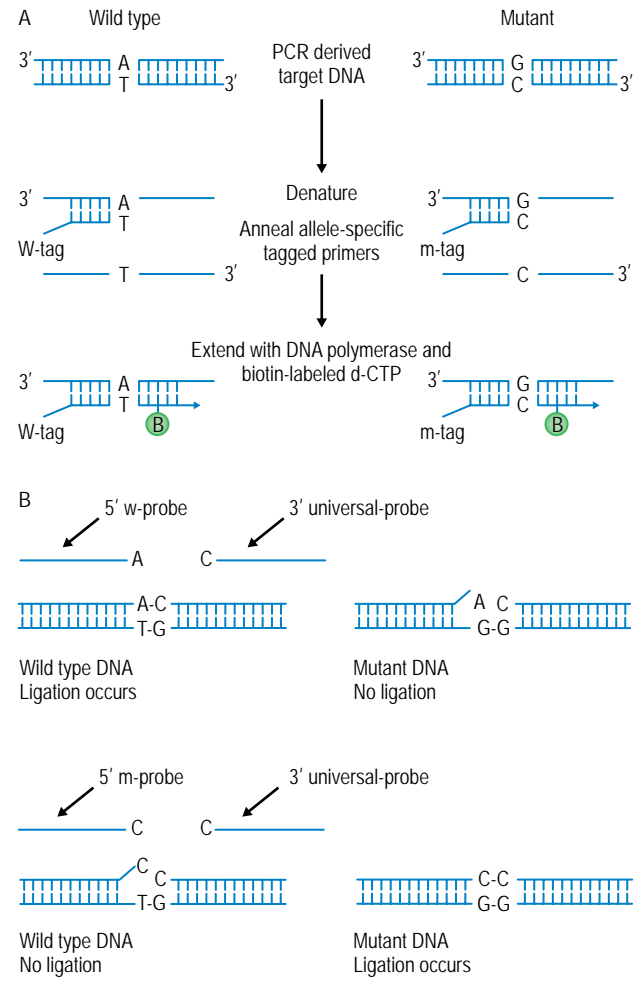

Fig. 101.8 Detecting known mutations. **(A)** Amplification refractory mutation system (ARMS). In this assay primers specific for the normal and mutant allele are synthesized. In its simplest form the presence or absence of amplification products can be detected on an agarose gel. The scheme depicted in the diagram shows tagged primers that allow capture of the amplification products on a solid phase and then detection by immunoenzyme recognition of the biotin label. **(B)** Oligonucleotide ligation assay (OLA). In this assay there are again specific oligonucleotides corresponding to exact matches with either the wild-type or mutant allele together with a 3' universal probe that exactly matches the adjacent sequence. After annealing the probes that match the target sequence may be ligated. The ligated products can be detected in various ways not shown in this diagram.

These will compete with one another, and the fluorescence emission will correspond to the oligo that exactly matches the target sequence. Both molecular beacons and TaqMan reactions are robust and, because they occur in solution without need for electrophoretic fragment separation, they lend themselves to scale-up automation. Limitations include the need for very precise probe design (which may require several rounds of optimization), the cost of custom fluorophore-tagged oligos, and the requirement for at least four oligos for each reaction.

Fig. 101.9 Detecting known mutations and SNPs. **(A)** Molecular beacons. Fluorophore-tagged oligonucleotides specific for the wild-type and mutant allele are hybridized during a PCR reaction to the DNA amplimers. The opening of the oligo hairpin allows the fluorophore to emit light at its characteristic wavelength, and the result is quantitatively detected as the PCR reaction progresses. **(B)** TaqMan reaction. Allele-specific fluorophore-tagged oligonucleotides are hybridized to single-strand DNA produced during a PCR reaction. Strand displacement leads to cleavage of the fluorophore and release from quenching. The intensity and wavelength of the emitted light is monitored during the course of the PCR.

Given that an increasing number of common mutations have been identified that may be screened in many unrelated patients, multiplex genotyping assays have begun to find wide application. One of the methods that has proved itself in both research and diagnostic applications is matrix-assisted laser desorption ionization time of flight (MALDI-TOF) mass spectroscopy.⁵⁴ In MALDI-TOF short amplification products are analyzed and the subtle differences in molecular weight are used to infer the base sequence. The method is highly sensitive, and by careful amplicon design can be used to analyze three to five amplicons per sample. By combining this analytical system with a single-base extension approach, multiplexing of up to 24-plex can be achieved.

MICROARRAYS

BAC and oligonucleotide arrays are having a revolutionary impact on RNA expression analysis, SNP genotyping and comparative genome hybridization. Array printing allows hundreds to thousands of BAC

DNAs or oligonucleotides to be spotted on activated glass surfaces.^{55–57} Distribution of oligos onto beads has also been used.^{58, 59} An alternative approach is direct synthesis of oligonucleotides on a silicon surface using photoactive chemistry and masking templates.⁶⁰ This process is very similar in principle to the fabrication of microelectronics devices, and so has given these arrays the nickname of ‘gene chips’. For expression analysis, cDNA ‘target’ derived from the tissue or cell source is labeled with fluorophores and used to determine complementary binding by massively parallel hybridization to the probes fixed on the array. Such arrays are extraordinarily useful for monitoring gene expression at thousands of loci in a single assay. Diagnostic and prognostic information about lymphomas,^{61, 62} leukemias,^{63, 64} and autoimmunity derived from expression arrays has already had a large impact on research and is likely to enter clinical diagnostic practice shortly.⁶⁵

Microarrays have been used both to assay for known mutations and polymorphisms and for the primary screening process – a kind of sequencing by hybridization. There are several limitations to this approach relating to the specificity of the hybridization, i.e., it is difficult to obtain conditions of specific and sensitive hybridization across many thousands of unique sites. Robust chemistries that can analyze standard sets of >500 000 SNPs in a single assay are now routine (Fig. 101.10). Nonamplified genomic DNA is too complex (i.e. the concentration of any particular sequence is too low) to be analyzed directly. High-throughput genotyping assays require an array-based readout and scalable, multiplex assay chemistry. This is extremely challenging because of the complexity of the human genome, i.e., any particular unique sequence in the mixture has a low molar concentration and because of the need for exquisite specificity at the single base level. An important general principle for achieving single base specificity is the detection of physically coincidental events.⁶⁶ This is exactly the route taken by PCR, in which specific annealing of both primers is required for the reaction to take place.

The molecular inversion probe (MIP) assay^{67, 68} and the GoldenGate assay⁶⁹ are examples that exploit a combination of linked specificity steps with a universal PCR. In both MIP and GoldenGate, specificity requires two-step recognition through annealing of 5′ and 3′ oligos flanking the SNP site. In MIP both the upstream and downstream locus-specific probes are physically linked in a single long oligonucleotide. The resulting enhanced binding kinetics allow lower concentrations of each probe and thus aids the multiplexing. MIP obtains allele discrimination by separating the reaction into nucleotide-specific reactions in which successful single base fill-in enables a subsequent ligation step. GoldenGate uses allele-specific primer extension in which the upstream and downstream probes are separate. But GoldenGate achieves high specificity by binding the target genomic DNA onto a bead, which can then be washed very stringently. Both MIP and GoldenGate use universal PCR to amplify the diverse locus-specific assays, a process that allows multiplexing at a level in which thousands of genomic loci are interrogated in parallel in the same reaction. The amplicons in this PCR reaction all contain short unique ‘address tags’ that are used as indicators for the individual assays. Both MIP and GoldenGate are read out through hybridization of the multiplex PCR products to a standardized array of oligonucleotides complementary to the address sequences. A severe problem in multiplex PCR is the potential formation of hybridization products, called primer dimers, between the various primers. The key to the universal PCR is the use of primers that include locus-specific 3′ and 5′ connected to universal primer sequences common to all assays in the

Fig. 101.10 Microarray genotyping. Oligonucleotides are printed or synthesized on a glass surface. Arrays based on oligonucleotide attachment to microbeads are also widely employed. Allele-specific hybridization is detected by the position in the array either employing locus-specific hybridization or address tags. Four methods are depicted that either detect standard sets of SNPs (**A**, **D**) or allow for custom assay design by the end-user (**B**, **C**). Each method is described in the text. (**A**) Whole genome sampling and amplification (WGA). End-labeled PCR products which constitute a sample from the genome are hybridized to oligo sets on standard chips. The oligos are organized into 'probe quartets' consisting of perfect matches (PM) and single-base mismatches (MM) for each allele, A and B. Separate quartets for the sense and antisense strand of DNA help to ensure specificity and in the actual assay these quartets are repeated three to five times on the chip. (**B**) This type of assay has been developed to test a standard panel of >1 M SNPs per sample. Molecular inversion probe (MIP). This assay is employed when genotyping several thousand SNPs that require custom design. The probe pools consist of very long oligonucleotides that allow the formation of a 'padlock' after allele-specific fill-in and ligation. The detection system involves a set of address oligos built into the original probes. After labeling these addresses are used to detect which allele is present in the target DNA by hybridization to a standard chip (not shown). (**C**) GoldenGate. This assay combines an allele-specific primer extension (ASPE) recognition with an address code system. Labeled universal primers (U1 and U2) assigned to each allele along with a fixed universal 3' primer (U3) are used to amplify a highly multiplexed reaction (up to ~1500-plex). Each SNP assay is identified with an address code sequence and the resulting amplification products are read out on a dense bead array (not shown).

Fig. 101.10—Cont'd (D) Infinium. This assay uses whole genome amplification (WGA) to increase the molar concentration of target DNA. ASPE on arrays of tagged microbeads allows allele discrimination and the resulting products are detected by immunostaining (signal amplification). This assay has been used for assays of >600 000 SNPs per sample.

primer pool. One approach, called homo-tag nondimer system (HANDS), uses reaction temperature variation to first allow locus-specific recognition and a subsequent switch to a higher annealing temperature that favors the universal primer reaction.

Whole genome sampling and amplification (WGSA) allows parallel amplification of short DNA segments (200–1100 bp) that are then labeled and hybridized to oligonucleotide probe arrays.⁷⁰ The oligonucleotides are specific for each allele of SNPs and the resulting hybridization intensities can be used to derive the genotypes. These assays are fixed in the sense that the investigator uses the information from a standardized array but cannot add SNPs for particular purposes. An alternative approach, incorporated in the Infinium assays (Illumina), involves the detection of allele-specific primer extension or single base extension products on a self-assembling high-density microbead array.⁷¹ In the Infinium assays genomic DNA is first subjected to whole genome amplification (WGA) and those products are hybridized to an array of locus-specific 50-mer capture probes. Either primer extension or ligation reactions on the array surface are used to accomplish allele discrimination. Signal amplification with methods familiar to users of ELISA assays are used to enhance the sensitivity. A distinct advantage of this class of assays is that the 'assay conversion' (percent SNPs that actually allow inference of the genotype in the final assay mixture) is very high. This allows great latitude in the selection of SNPs, and thus might prove highly useful in assays of human mutations.

BIOINFORMATICS

Bioinformatics has emerged as a fundamental discipline in molecular biology as enormous DNA and protein sequence databases, linkage maps, physical maps, and other integrated data sets have been generated by individual laboratories and the human genome project. The growing number of genetic loci that are already known to be important in immunological disease renders it critical that both research and diagnostic

laboratories make maximal use of automated processes in sample archiving, data acquisition, data analysis, and reporting.

INTERNAL DATABASES AND DATA ACQUISITION

Laboratory information management (LIM) systems are widespread and each laboratory must deal with the generic operational problems of sample accession, tracking, and reporting. DNA diagnostic laboratories have several unique problems and requirements that deserve comment. Relational databases (usually implemented on Oracle or SQL servers) should integrate sample accession, physical archive, quality control, and genotype information. Automated data acquisition is an important component of DNA sequencing and genotyping. Instrument-specific and secondary base-calling programs are necessary for data interpretation. More sophisticated statistical models of sequencing and genotyping data are greatly improving the ability to handle datasets per individual that would be far too large for manual analysis.⁷² Automated procedures for exporting data files to analytical software and data archiving on indelible media are also important issues. The number of patient-specific data records and the complexity of relationships in family-based testing make it difficult for manual processes to achieve the required reliability.

DATA INTERPRETATION AND PUBLIC SEQUENCE DATABASES

Computer-based methods for genotype and DNA sequence data interpretation are necessary for efficiency and cost-effectiveness. Estimation of genetic risks based on genotype data requires a knowledge of specialized statistical procedures whose description is beyond the scope of this chapter. The development of specialized training programs in molecular genetics and molecular genetic pathology by the American Boards of Medical Genetics and Pathology⁷³ highlights the recognition by professional groups that this area of clinical testing is exceptionally complex. Although inferences made about disease diagnosis and carrier status

based on direct detection of mutations are inherently categorical, data interpretation should incorporate known genotype–phenotype correlations, variable disease expression/severity, incomplete penetrance, gender-specific risk, and other available data. In the future, as DNA testing is employed in the assessment of more complex traits such as autoimmune and neoplastic diseases, genotype data will perhaps be expressed as ‘relative risk’ and incorporate gene–gene and gene–environment interactions. The reliability of these estimates will require standard data acquisition algorithms and constant updating of population-based data.

The reference human genome sequence is complete (<http://genome.ucsc.edu/>) and has fueled the rapid expansion of clinical sequencing and genotyping. Diagnostic laboratories must actively use information contained in the public sequence databases to interpret the biological consequences of mutations and polymorphisms. There are at least several broad databases that are likely to have an important role over the next decade: (1) GenBank, which contains the nonredundant cDNA and protein sequences, finished human genomic sequences (<http://www.ncbi.nlm.nih.gov/entrez/>); (2) dbSNP, which contains more than 10 000 000 common single-nucleotide polymorphisms; and (3) the Human Mutation Database, which assembles mutation information on known disease loci (<http://www.hgmd.cf.ac.uk/ac/index.php>). Public tools are available for DNA sequence comparisons of patient-specific data with the reference sequences (<http://www.ncbi.nlm.nih.gov/BLAST/>). The Smith–Waterman algorithm estimates local sequence similarity. The most common implementations employ variations on the basic alignment search tool (BLAST) which quantifies local similarity using the maximal segment pair (MSP) score. A very large database of SNPs genotyped in four reference population samples (northern Europeans from Utah; Yoruba from Ibadan, Nigeria; Han Chinese from Beijing; and Japanese from Tokyo) was produced by the International Haplotype Map Project (www.hapmap.org). This database is expected to enable mapping of genes that underlie complex traits such as human autoimmune diseases. The reference genotypes and their associated haplotypes give important information about the short-range correlations between markers (called linkage disequilibrium) and allow the selection of marker sets that efficiently capture most of the genetic information in a population sample.^{74,75}

Interpretation of sequence and genotype information is the final output of a molecular diagnostic test. If a mutation has been observed in the proband and other family members are tested, then the expectation is that the mutation will exactly segregate with the disease. An example would be testing for a mutation in X-linked SCID in two brothers. The causal mutation will be present in both. When the proband is the only affected individual, then one may look to the research literature and locus-specific public databases (http://bioinf.uta.fi/base_root/mutationdatabases.php) to determine whether the specific mutation has previously been observed in another affected person. However, it is not uncommon to find a mutation that has not previously been observed, and as mutation analysis by DNA sequencing becomes more common this will be a frequent occurrence. Assessment of the functional consequence of a newly observed sequence variant is problematic as there is no guarantee that the variant is anything more than a rare, but neutral, polymorphism. Nonsense and frameshift mutations are relatively clear. Mutations in sites flanking coding exons known to be required for splicing are easily categorized. Missense substitutions are more difficult. Several methods based on sequence conservation and the chemical properties of amino acids have been developed. These are available in software called SIFT (Sorting Intolerant From Tolerant, <http://blocks.fhcrc.org/sift/SIFT.html>)

KEY CONCEPTS

PRINCIPLES OF MOLECULAR DIAGNOSTICS

- >> DNA diagnostics can play an important role in the diagnosis of specific diseases in affected patients and in genetic risk assessment for their family members.
- >> Genotyping can be used to conduct prenatal diagnoses.
- >> Prenatal diagnosis may be used not only for elective termination of pregnancy but also for treatment planning.
- >> Provision of genetic testing results to patients and their families carries responsibilities for sensitivity and confidentiality.

and PolyPhen (<http://coot.embl.de/PolyPhen/>). As the growing database of protein crystal structures (<http://www.ncbi.nlm.nih.gov/Structure/>) is extended, alignment methods, called ‘threading,’ will permit evaluation of the effect of an amino acid substitution on catalytic and interaction sites.

RECOMMENDATIONS FOR USE

Molecular diagnostic techniques have a wide range of potential applications in clinical immunology. DNA diagnostic procedures are used to (a) perform HLA genotyping; (b) analyze neoplastic disease; (c) provide identification or DNA ‘fingerprinting’; (d) monitor bone marrow engraftment; (e) establish a genetic diagnosis in a symptomatic individual; (f) determine the risk of occurrence of a disease in offspring; and (g) to establish a prenatal diagnosis. The use of DNA analysis for HLA typing is described in Chapter 5. DNA techniques are used in leukemias and lymphomas, primarily for investigation of cell lineage, proliferative clonality, and measurement of residual abnormal cells after therapy. Molecular analysis, and especially molecular cytogenetic analysis, is important in guiding initial and follow-up therapy (see Chapters 76 and 77).

GENETIC COUNSELING

There is a role for molecular testing in genetic risk assessment in primary immune deficiencies.⁷⁶ Testing is usually applied to families whose risk of recurrence has been signaled by the birth of an affected child. Almost every case has to be treated as a problem requiring initial mutation identification. The rarity of the individual disorders and the frequent occurrence of new mutations in the X-linked diseases preclude population-wide heterozygote screening.

In the recessive immune deficiencies, carrier status is assumed in the parents once an affected child has been diagnosed. A much lower risk of having an affected child is attached to other carriers in a family, as their mates are unlikely to bear a mutant disease gene allele unless they are themselves lineal relatives of the index case. In the X-linked immune deficiencies the situation is strikingly different. In those cases the origin of mutation should be investigated to ascertain the carrier status of all the at-risk women. In a family with a single affected child carrying the diagnosis of an X-linked immune deficiency, there is a substantial risk that

the mother is a carrier. The risk of carrier status in such women is 67–80%, depending on the locus. After the birth of a second affected child, and if the mutation has not been directly identified, the mother would be considered an obligate carrier (although somatic mosaicism is also a less likely possibility^{77–79}). Women sharing a common lineage between two affected individuals in an extended pedigree, e.g., affected first cousins, would also be considered obligate carriers.

Genetic information, like any medical information, may be unsettling to patients and families. However, there are some special considerations that attach themselves to genetic testing, and practitioners need to be aware of this and appropriately cautious (http://www.ornl.gov/sci/techresources/Human_Genome/elsi/elsi.shtml). A fundamental principle of genetic testing for clinical or research purposes should be informed consent. The testing itself, as well as the plan for sample preservation or disposal, should be described in detail to the patient and family and, where appropriate, written consent obtained. An unintended consequence of genotyping may be to reveal nonpaternity of the stated father. The possibility that this might emerge from genetic testing should be sensitively conveyed to the prospective clients and may be a reason for avoiding further laboratory testing. In addition, pedigree analysis may uncover unsuspected risk in other family members who may not be seeking genetic information. Some have argued for a 'duty to inform' at-risk family members. Prospective testing, particularly carrier testing, in children before the age of individual consent raises troubling issues that have not been resolved. The latent possibility of employment or insurance discrimination with the incorporation of genotype information into the medical record is another area receiving a great deal of attention. It is important to emphasize in the presentation of the information that the occurrence of new mutation is a natural accident. Where possible, it is strongly preferred that genetic risk information be provided by professionals with experience and training in clinical genetics. There is currently a great deal of concern for the preservation of confidentiality relating to all genetic information.

PRENATAL DIAGNOSIS

Prenatal diagnosis is accomplished either by direct measurement of the defective function, e.g., enzyme activity in ADA deficiency, or by genetic methods. Because many immune disorders affect cells of the blood system exclusively, the former would mean fetal blood sampling. This is accompanied by a higher risk of fetal loss than either amniocentesis or chorion villus sampling (CVS). DNA-based methods may be equally applied to CVS samples or amniocytes. An important technical consideration in the use of CVS is examination for maternal cell contamination, as this could lead to an erroneous diagnosis. DNA diagnosis may employ linkage analysis, in which an inference is made using neighboring DNA markers about whether the developing fetus has inherited the same mutated chromosomal segment(s) as the index case. However, direct mutation identification in the index case and then use of a direct mutation detection procedure in the developing fetus is always preferred. There is now much more experience with pre-implantation genetic diagnosis (PGD), but this remains a highly specialized and expensive procedure.⁸⁰ PGD involves the removal of a single blastomere at the eight-cell stage. PCR methods are used to carry out genetic analysis. Recent publications have illustrated the use of PGD to select offspring with compatible HLA types for siblings requiring hematopoietic stem cell transplantation.^{81, 82}

Prenatal diagnosis is used for either pregnancy management or treatment planning. In the case of a positive diagnosis of a primary immune deficiency, the couple should then have access to detailed information from an experienced clinical immunologist regarding the current treatment options and prognosis. The perception of the burden of disease may be colored by a previous bad therapeutic outcome caused by late diagnosis and its consequent complications. Prenatal diagnosis allows appropriate treatment planning to be carried out for isolation, prospective intravenous immunoglobulin therapy, prophylactic antibiotic therapy, and planning for bone marrow stem cell transplantation (Chapter 83).

Despite current successes in clinical management of immune deficiency, clinicians involved in providing prenatal genetic services should be prepared to be supportive toward the couple regarding decisions made to terminate an affected pregnancy. Although the ideal of genetic medicine is nondirective counseling, it has been pointed out that by offering to conduct prenatal testing, physicians are communicating a value judgment about the severity, treatability, and burden of a disease. Physicians involved in prenatal diagnosis for genetic immune deficiency should be aware of the particular couple's balance in decision making, opinions or pressures from extended family, and religious outlook.

LABORATORY STANDARDS AND REPORTING

All US laboratories providing any clinical data are subject to the regulatory requirements embodied in the Clinical Laboratory Improvement Amendments of 1988 (CLIA88).⁸³ Research laboratories that do not report patient-specific information are specifically exempt, but CLIA88 is clearly intended to preclude an arrangement where research laboratories perform diagnostic tests and prenatal diagnoses. CLIA88 mandates biannual laboratory inspections, quality control, quality assurance, proficiency testing, and personnel training standards. The American College of Medical Genetics has also produced guidelines for diagnostic laboratories conducting molecular genetics testing (<http://www.faseb.org/genetics/acmg/stds/stdsmenu.htm>). A clear argument can be made for the cost-effectiveness of prenatal diagnosis for such diseases, but it is unknown whether family analysis and carrier detection are ultimately effective in either reducing the number of affected individuals or improving their clinical outcome.

FUTURE DIRECTIONS

The next decade will bring further improvements in our ability to identify family-specific mutations for all the known disease genes. Sequencing technology will move increasingly to microscale formats, perhaps even employing 'nanotechnology' devices that integrate both chemical reactions and analytical devices. Highly parallel sequence analysis should increase production rates and reduce the cost per sample. DNA arrays for genotyping and mutation screening should ultimately replace current single-assay formats. As our understanding of the role of polymorphisms in disease risk increases the importance of low-cost, high-throughput genotyping of standard variant panels will also increase. The importance of bioinformatics in data analysis will become increasingly apparent as large amounts of individual genotype data are produced. International mutation databases will play an important role in both diagnosis and

prognosis. New statistical approaches will be needed to exploit fully the potential of dense SNP marker maps for estimation of disease risk. Technical improvements should ultimately permit prospective screening of newborns for the primary immune deficiencies. Although rare, these are treatable disorders whose prognosis would be altered by early diagnosis before the onset of serious infection. In aggregate, the birth incidence is sufficient to merit screening if the techniques could be interfaced with current state screening programs. Screening for premalignant genotypic changes in peripheral blood might also be a reality one day. Careful clinical studies, including examination of the costs and benefits of mass screening programs, will be essential.

Appendix:

Selected CD molecules and their characteristics

1

Selected CD molecules and their characteristics

CD molecule	Predominant distribution	Identity/function
CD1a–e	Thymocytes, subset of lymphocytes, antigen-presenting cells	MHC class I-like molecules; presentation of non-peptide antigens to T cells; thymic T-cell development
CD2	T cells	Binds to LFA-3; receptor for CD48; T-cell activation; adhesion
CD3	T cells	T-cell signaling complex; associated with T-cell receptor (TCR)
CD4	T-cell subset	TCR co-receptor; interacts with MHC class II molecules on antigen presenting cells; identifies T cells with helper function; signal transduction
CD5	Most T cells, thymocytes, B-cell subset	Binds to CD72; regulation of cell proliferation/activation; identifies B-1 B-cell subset
CD6	Thymocytes, T cells, B-cell subset	Binds CD166 (ALCAM); adhesion; mediates binding of developing thymocytes with thymic epithelial cells; thymic development; T-cell activation
CD7	Pluripotent hematopoietic cells, thymocytes, T cells	T-cell and NK-cell development
CD8	T-cell subset	TCR co-receptor; interacts with MHC class I molecules on antigen-presenting cells; identifies T cells with cytotoxic function
CD10	B cells	Neutral endopeptidase; enkephalinase; B-cell development; common acute lymphoblastic leukemia antigen (CALLA)
CD11a	Leukocytes	α chain of LFA-1; pairs with CD18; interacts with ICAM; adhesion and cellular migration
CD11b	Monocytes, granulocytes, NK cells	α chain of complement receptor 3 (CR3); pairs with CD18; adhesion molecule
CD11c	Monocytes, granulocytes, NK cells	α chain of complement receptor 4 (CR4); pairs with CD18; adhesion molecule

Continued

Selected CD molecules and their characteristics—cont'd

CD molecule	Predominant distribution	Identity/function
CD14	Granulocytes, monocytes/macrophages	Receptor for LPS/LPB complex; myeloid differentiation antigen; cell activation
CD16a,b	NK cells, monocytes/macrophages, neutrophils	FcγRIIIA and FcγRIIIB (low-affinity IgG receptors-type III); phagocytosis; ADCC
CD18	Leukocytes	β chain of β ₂ -integrin molecules, including LFA-1, CR3, and CR4; pairs with CD11a, b, and c
CD19	B cells	BCR co-receptor; signal transduction; complexes with CD21
CD20	B cells	Role in B-cell activation/differentiation
CD21	B cells; follicular dendritic cells	Complement receptor type 2 (CR2); C3d receptor; B-cell co-receptor subunit; EBV receptor
CD22	B cells	Associates with BCR; signaling; regulation of B-cell activation; adhesion
CD23	B cells, macrophages, eosinophils, platelets, follicular dendritic cells	FcεRII; (Low-affinity IgE receptor)
CD24	Leukocytes	Heat-stable antigen; co-stimulation; adhesion
CD25	Activated T cells and B cells	α chain of IL-2 receptor, low-affinity IL-2 binding; signaling for cell proliferation/differentiation
CD26	Activated T cells and B cells; macrophages	Dipeptidyl peptidase; role in extracellular adhesion; cell activation
CD27	T cells; B cell subset	Co-stimulation; T-cell proliferation, memory B cells
CD28	T cells	Binds B7-1 (CD80) and B7-2 (CD86); T-cell co-stimulation; signal transduction
CD29	Leukocytes	Integrin β ₁ chain; pairs with CD49a-CD49f to form VLA-1-VLA-6 integrins, respectively; adhesion; signal transduction; development
CD30	Activated B cells and T cells	Binds to CD153; T cell activation/regulation/differentiation
CD31	Monocytes, granulocytes, platelets, endothelial cells, B cells	PECAM-1; Binds to CD38; adhesion; signal transduction
CD32	B cells, monocytes/macrophages, granulocytes, eosinophils	FcγRII (low-affinity IgG receptor-type II) phagocytosis; ADCC; B cell regulation
CD33	Myeloid progenitors, granulocytes	Binds sialic acid
CD34	Hematopoietic progenitor cells; capillary endothelium	Mucosialin; binds to CD62L; adhesion
CD35	Leukocytes; erythrocytes	Complement receptor 1 (CR1); C3b and C4b receptor; phagocytosis
CD36	Monocytes/macrophages; endothelium; platelets	Binds oxidized LDL; scavenger receptor; binds apoptotic cells; adhesion and endocytic receptor; GPIIb; platelet adhesion and aggregation
CD38	NK cells; T- and B-cell subsets; monocytes	Binds CD31; cyclase; hydrolase; cell activation

Selected CD molecules and their characteristics—cont'd

CD molecule	Predominant distribution	Identity/function
CD40	B cells; antigen-presenting cells	Binds CD154 (CD40 ligand); B-cell proliferation differentiation, and survival; T-cell co-stimulation
CD41	Megakaryocytes/platelets	Glycoprotein IIb; a IIb integrin chain; binds fibronectin, fibrinogen, von-Willebrand factor, thrombospondin; extracellular adhesion; platelet aggregation
CD43	Leukocytes (except resting B cells)	Leukocyte sialoglycoprotein; may bind CD54; signal transduction; adhesion; anti-adhesion
CD44	Leukocytes; memory T cells; erythrocytes	Binds hyaluronan (H-CAM), collagen, fibronectin, laminin, osteopontin; extra- and intercellular adhesion; T-cell co-stimulation; leukocyte homing
CD45	Leukocytes (pan-leukocyte marker)	Protein tyrosine phosphatase; cell differentiation; lymphocyte signal transduction and activation
CD45RA	Naive T-cell marker (in conjunction with CD62L); B cells, monocytes	CD45 isoform
CD45RB	B- and T-cell subsets, monocytes/macrophages, granulocytes	CD45 isoform
CD45RO	Memory and activated T cells; B cells, B cells, monocytes/macrophages	CD45 isoform
CD46	Hematopoietic cells	Membrane cofactor protein (MCP); binds to C3b and C4b and regulates complement pathway
CD47R	Leukocytes; endothelium	Integrin-associated protein (IAP); leukocyte migration, extravasation and activation
CD48	Leukocytes (not neutrophils)	Binds CD2; adhesion; co-stimulation
CD49a-f	Various distributions	Integrin α 1-6 chain; binds to CD29 to form VLA-1 to VLA-6; binds extracellular matrix components such as fibronectin, laminin, collagen (CD49D binds VCAM-1, fibronectin, MadCAM-1, invasin); lymphocyte homing; extracellular adhesion; embryonic development
CD50	Thymocytes, B cells, T cells, monocytes, granulocytes	ICAM-3; adhesion
CD51	Platelets/megakaryocytes, granulocytes, monocytes, T cells	Integrin α chain; associates with CD61; binds vitronectin, fibronectin, fibrinogen; extracellular adhesion; T-cell co-stimulation; epithelial inflammatory response
CD52	Leukocytes	GPI linked, signaling, defined by CAMPATH-1
CD54	Broad distribution; increased on activated leukocytes	ICAM-1; binds LFA-1; adhesion; leukocyte transendothelial migration, rhinovirus receptor
CD55	Hematopoietic cells and some nonhematopoietic cells	Decay accelerating factor (DAF); binds complement fragment C3b; regulation of complement activation
CD56	NK cells	NKH-1; adhesion

Continued

Selected CD molecules and their characteristics—cont'd

CD molecule	Predominant distribution	Identity/function
CD57	NK cells, T-cell subset, B cells, monocytes	Oligosaccharide expressed on cell surface glycoproteins
CD58	Hematopoietic cells and nonhematopoietic cells	LFA-3; binds CD2; adhesion; lymphocyte co-activation
CD59	Hematopoietic cells and non-hematopoietic cells	Binds complement components C8 and C9 and regulates assembly of complement membrane attack complex
CD61	Platelets/megakaryocytes, macrophages	Integrin β_3 subunit; associates with CD41 or CD51
CD62E	Endothelium	ELAM-1 or E-selection; binds sialyl-Lewis X; adhesion; mediates rolling interaction of neutrophils on endothelium and neutrophil extravasation
CD62L	B cells, T cells, monocytes, NK cells	LECAM-1, LAM-1 (or L-selectin); binds CD34 and GlyCAM; adhesion; mediates rolling interactions with endothelium and cell extravasation
CD62P	Platelets/megakaryocytes, endothelium	P-selectin; binds sialyl-Lewis X; mediates interaction of platelets with neutrophils and monocytes; mediates rolling interaction of neutrophils with endothelium
CD64	Monocytes/macrophages	Fc γ R1 (High affinity IgG receptor)
CD68	Monocytes/macrophages	Macrosialin; early activation antigen; role in phagocytic activity
CD69	Activated T cells, B cells, macrophages, NK cells	Early activation antigen; co-stimulation
CD70	Activated B and T cells; macrophages	Binds to CD27; co-stimulation
CD71	Activated leukocytes	Transferrin receptor; cell activation
CD72	B cells	Ligand for CD5; B-cell activation and differentiation; co-stimulation
CD73	B- and T-cell subsets	Ecto-5' nucleotidase; allows nucleoside uptake
CD74	MHC class II-expressing cells	MHC class II-associated invariant chain; involved in antigen processing and peptide presentation in antigen-presenting cells
CD77	Germinal center B cells	
CD79a,b	B cells	Ig α , Ig β ; components of BCR complex that mediate signal transduction
CD80	Monocytes/macrophages, dendritic cells, activated B cells	B7-1; ligand for CD28 and CTLA-4; T-cell interaction with antigen-presenting cells; co-stimulation
CD81	Lymphocytes	Associates with CD19 and CD21 to form B-cell co-receptor complex; co-stimulation; adhesion
CD86	Monocytes, activated B cells	B7-2; ligand for CD28 and CTLA-4; T cell interaction with antigen-presenting cells; co-stimulation
CD87	Granulocytes; monocytes/macrophages, activated T cells	Urokinase plasminogen activator receptor
CD88	Granulocytes, macrophages, mast cells	Complement component fragment C5a receptor
CD89	Monocytes/macrophages, granulocytes, B and T cell subsets	Fc α R (IgA receptor)

Selected CD molecules and their characteristics—cont'd

CD molecule	Predominant distribution	Identity/function
CD91	Monocytes	α_2 -macroglobulin receptor
CD94	NK cells, T-cell subset	Inhibits killing
CD95	Broad distribution	Fas or Apo-1; induces apoptosis after being bound by Fas ligand
CD97	Activated B and T cells, monocytes, PMN	Activation antigen
CD102	Resting lymphocytes, monocytes, endothelial cells	ICAM-2; binds LFA-1 (CD11a/CD18); adhesion; T-cell co-stimulation
CD103	Intraepithelial lymphocytes, T-cell subset	aE integrin; T-cell development and co-stimulation
CD104	Epithelial cells, Schwann cells	β_4 -integrin; epidermal adhesion to basement membrane
CD105	Endothelial cells, bone marrow cell subset, activated macrophages	Endoglin; adhesion
CD106	Endothelial cells	VCAM-1; ligand for VLA-4; lymphocyte adhesion; embryonic development
CD107a,b	Epithelial cells, subsets of monocytes, granulocytes, and lymphocytes	LAMP-1 and LAMP-2; adhesion
CD110	Hematopoietic stem cells, megakaryocytes, platelets	Thrombopoietin receptor; megakaryocyte proliferation and differentiation
CD114	Granulocytes	G-CSF receptor; regulates granulopoiesis
CD115	Monocytes/macrophages	M-CSF receptor; cell differentiation
CD116	Monocytes, neutrophils, eosinophils	GM-CSF α chain receptor; cell differentiation
CD117	Hematopoietic progenitors	c-kit; stem cell factor (SCF) receptor; hematopoietic cell differentiation
CD118	Broad distribution	Type 1 interferon (interferon- α/β) receptor
CD119	Broad distribution	Interferon- γ receptor
CD120a	Hematopoietic cells, nonhematopoietic cells, myeloid cells	TNF receptor-type 1; signal transduction; apoptosis
CD120b	Hematopoietic cells, nonhematopoietic cells, myeloid cells	TNF receptor-type II; signal transduction, apoptosis
CD121a	Thymocytes, T-cell subset, fibroblasts, epithelial cells, and brain cells	IL-1 receptor-type I; signal transduction
CD121b	T-cell subset, myeloid cell subsets	IL-1 receptor-type II
CD122	NK cells, T-cell and B-cell subset	IL-2 and IL-15 receptor β chain; signal transduction; regulation of lymphocyte development, differentiation, activation and proliferation
CD123	Bone marrow stem cells, granulocytes, monocytes, megakaryocytes	IL-3 receptor α chain; cell development and differentiation
CD124	Mature B and T cells, hematopoietic precursor cells	IL-4 receptor; signal transduction; lymphocyte development, activation, differentiation and proliferation
CD125	Eosinophils, basophils, B cell subset	IL-5 receptor; eosinophil and B-cell growth and differentiation
CD126	Activated B cells, plasma cells, T cells, granulocytes, monocytes/macrophages; also expressed on epithelial cells, fibroblasts, hepatocytes, and neural cells	IL-6 receptor α chain; regulation of B- and T-cell differentiation and function; hematopoiesis
CD127	Bone marrow lymphoid precursors, pro-B cells, T cell precursors, T-cell subset, monocytes	IL-7 receptor α chain; signal transduction; B- and T-cell proliferation and differentiation

Continued

Selected CD molecules and their characteristics—cont'd

CD molecule	Predominant distribution	Identity/function
CD128	Neutrophils, basophils, T-cell subset	IL-8 receptor; neutrophil activation and migration
CD129	T cells	IL-9 receptor α chain; T-cell proliferation
CD130	Broad distribution	IL-6 receptor β chain (with CD126); signal transduction
CD131	Lymphocytes, granulocytes, monocytes	IL-3, IL-5 and GM-CSF receptor; common β chain; signal transduction; see CD123 and CD125
CD132	Lymphocytes	Common γ chain of high-affinity receptor for IL-2 (with CD25 and CD122), IL-4 (with CD124), IL-7 (with CD127), IL-9 (with CD129), and IL15 (with CD122) receptors; signal transduction
CD134	Activated T cells	OX-40 antigen of TNFR superfamily (binds OX-40 ligand); T-cell–B-cell interaction and T-cell co-stimulation
CD135	Lymphoid and myeloid cell progenitor subsets	Flt3 ligand receptor; development of myeloid and lymphoid progenitors
CD137	Activated T cells	4-1BB; binds 4-1BB ligand and extracellular matrix components; T-cell–B-cell interaction and T-cell co-stimulation; extracellular adhesion; signal transduction
CD138	B cell subset, plasma cells	Syndecan-1; binds interstitial matrix proteins; B-cell–matrix interactions
CD140a,b	Endothelial cells	PDGF receptor α and β chain; embryonic development; signal transduction; chemotaxis
CD141	Endothelium	Thrombomodulin (binds thrombin); regulates coagulation
CD142	Endothelium	Tissue factor; binds plasma factors VII/VIIa; hemostasis, coagulation, and angiogenesis
CD143	Endothelium	Angiotensin-converting enzyme (ACE); binds angiotensin 1; regulates blood pressure
CD144	Endothelium	VE-cadherin; cell–cell adhesion; maintenance of endothelium integrity
CD146	Activated T-cell subset	Mel-CAM, adhesion molecule during development
CD150	T- and B-cell subsets	Surface lymphocyte activation marker (SLAM); B-cell–T-cell interaction; co-stimulation
CD151	Not defined	PETA-3; regulates platelet aggregation and mediator release
CD152	Activated T cells	CTLA-4; binds B7-1 (CD80) and B7-2 (CD86); T-cell co-stimulation-negative signal
CD153	T cells	CD30 ligand; T-cell activation, differentiation, and regulation
CD154	Activated T cells	CD40 ligand; T-cell co-stimulation
CD156a	Leukocytes, B cells	Transmembrane glycoprotein; disintegrin and metalloproteinase domain (ADAM) family member; leukocyte adhesion and protease function; infiltration of myelomonocytic cells

Selected CD molecules and their characteristics—cont'd

CD molecule	Predominant distribution	Identity/function
CD156b	Broad distribution	TNF- α -converting enzyme (TACE); disintegrin and metalloproteinase domain (ADAM) family member; cleaves TNF and transforming growth factor- α from cell surface, thereby releasing soluble form
CD158	NK cells	Killer cell immunoglobulin (Ig)-like receptors (KIR); family of molecules that inhibit NK cytotoxic activity
CD159a	NK cells	NKG2A (killer cell lectin-like receptor)
CD161	NK cells	Natural killer cell receptor-P1; target cell recognition; NK cell activation
CD162	Granulocyte and T cell subsets	P-selectin glycoprotein ligand-1 (PSGL-1); adhesion
CD166	Activated T cells, B cells	ALCAM; binds CD6; T-cell activation; thymocyte development
CD167a	Epithelial cells	Discoidin domain receptor 1 (DDD1); tyrosine kinase receptor; binds to collagen; cell-cell contact and adhesion
CD178	Activated T cells; various tissue cells	Fas ligand (ligand for CD95); binding to Fas triggers apoptosis
CD179a	Pro-B and pre-B cells	VpreB; forms surrogate light chain with CD179b; early B-cell differentiation
CD179b	Pro-B and pre-B cells	λ 5; forms surrogate light chain with CD179a; early B-cell differentiation
CD180	B cells	RP105; toll-like receptor family; regulates B-cell recognition and signaling of LPS
CD183	Effector/memory T cells, NK cells, eos	CXCR3 receptor for interferon-inducible chemokines IP10, Mig, and I-TAC; chemotactic migration of effector T cells into areas of inflammation
CD184	Leukocytes; hematopoietic progenitors	CXCR4 receptor for chemokines such as stromal cell-derived factor-1 (SDF-1) (fusin); chemotaxis; HIV-1 co-receptor
CD195	Broad distribution; myeloid cells, lymphocytes, T lymphocytes, neurons, epithelium, endothelium	CCR5 receptor for chemokines such as macrophage inflammatory proteins, MIP-1a and MIP-1b, and RANTES; chemotaxis; HIV-1 co-receptor
CDw197	Lymphoid tissues, B cells, T-cell subset	CCR7 chemokine receptor; chemotaxis; T-cell homing and migration
CD201	Endothelial cells	Protein C receptor; coagulation
CD204	Myeloid cells, monocytes/macrophages	Macrophage scavenger receptor-1 (MSR1); mediates binding, internalization and processing of various negatively charged macromolecules
CD206	Dendritic cells, macrophages, myeloid cells, endothelial cells	Mannose receptor, C-type 1; binds microorganisms; phagocytosis
CD207	Dendritic cells, Langerhans' cells	Langerin; mannose receptor; phagocytosis and internalization of antigen for processing
CD208	Dendritic cells	DC-LAMP
CD209	Dendritic cells	DC-SIGN
CDw210	Broad distribution	IL-10 receptor α and β chain;

Continued

APPENDICES

Selected CD molecules and their characteristics—cont'd

CD molecule	Predominant distribution	Identity/function
CD212	T cells, NK cells	IL-12 receptor β_1 chain;
CD213a1,a2	Lymphocytes, bronchial epithelial and smooth muscle cells	IL-13 receptor α_1 and α_2 chains
CDw217	Activated T-cell subset	IL-17; cytotoxic T-lymphocyte-associated serine esterase 8; stimulates cell activation; induces osteoclast differentiation factor (ODF)
CD220	Broad distribution	Insulin receptor; stimulates glucose uptake
CD molecule	Predominant distribution	Identity/function
CD221	Broad distribution	Insulin-like growth factor 1 receptor; cell signaling; activation, and differentiation
CD222	Broad distribution	Mannose-6-phosphate receptor; insulin-like growth factor-2 receptor
CD226	NK cells, platelets, monocytes, T-cell subset	Platelet and T-cell activation antigen 1 (PTA1); adhesion
CD233–241	Erythrocytes	Various erythrocyte membrane antigens, including blood group-associated glycoproteins
CD242	Erythrocytes	ICAM-4
CD246	T cells	TCR or CD3 ζ chain; associated with TCR and CD3; couples TCR recognition with T-cell signaling
CD247	T cells	T cells ζ chain of the TcR
CD252	Activated B cells	OX40 ligand
CD253	Activated T cells	TRAIL, death receptor
CD254	Activated T cells, LN and BM stroma	RANK ligand
CD256	Monocytes, macrophages	APRIL, binds TACI and BCMA
CD261	Activated T cells, peripheral leukocytes	TRAIL-R2, DR5, death receptor
CD262	Peripheral lymphocytes	TRAIL-R1, DR4, death receptor
CD263	Peripheral lymphocytes	TRAIL-R3, DcR1, death receptor
CD264	Peripheral lymphocytes	TRAIL-R4, DcR2, death receptor
CD265	Broad distribution	RANK
CD267	B cells, activated T cells	TACI
CD268	B cells	BAFFR, binds BLyS, mature B-cell survival
CD269	Mature B cells	BCMA, binds APRIL and BAFF, B-cell survival and proliferation
CD275	B cells, dendritic cells, monocytes	ICOSL, costimulation, cytokine production
CD278	Activated T cells	ICOS, T-cell co-stimulation
CD257	Activated monocytes	BLyS, BAFF, binds TACI, BCMA, BAFFR, induces B-cell proliferation

ADCC, antibody dependent cellular cytotoxicity; ALCAM, activated leukocyte cell adhesion molecule; BCR, B cell receptor for antigen; EBV, Epstein-Barr virus; ELAM, endothelial leukocyte adhesion molecule; G-CSF, granulocyte colony-stimulating factor; GM-CSF, granulocyte macrophage colony-stimulating factor; ICAM, intercellular adhesion molecule; LAM, leukocyte adhesion molecule; LAMP, latent membrane protein; LDL, low density lipoproteins; LECAM, lymphocyte endothelial cell adhesion molecule; LFA, lymphocyte function antigen; LPB, lipopolysaccharide binding protein;

LPS, lipopolysaccharide; M-CSF, macrophage colony-stimulating factor; MHC, major histocompatibility complex; NK cells, natural killer cells; PDGF, platelet-derived growth factor; PECAM, platelet endothelial cell adhesion molecule; PETA, platelet-endothelial cell tetraspan antigen; TCR, T-cell receptor for antigen; TNF, tumor necrosis factor; TNFR, tumor necrosis factor receptor; VCAM, vascular cellular adhesion molecule; VLA, very late antigen.

This list was adapted from the results of the Eighth International Workshop on Human Leukocyte Differentiation Antigens (HLDA8) held in Adelaide, Australia, in December 2004 (Cell Immunol 2005; 236: 1–187).

Appendix: Laboratory reference values

2

Immunoglobulin levels (age-related reference ranges; see Chapter 96)

Chemokines

Class	Systemic name	Chemokine		Receptor(s)	Receptor(s) expressed on	Receptor class
CXC (α)	CXCL1	GRO- α , MGSA	Growth-related oncogene- α	CXCR2 Duffy	NK, M, N, Ba Erythrocytes	CXC XC
	CXCL2	GRO- β	Growth-related oncogene- β	CXCR2	NK, M, N, Ba	CXC
	CXCL3	GRO- γ	Growth-related oncogene- γ	CXCR2	NK, M, N, Ba	CXC
	CXCL4	PF4	Platelet factor 4			
	CXCL5	ENA-78	Epithelial cell derived neutrophil attractant-78	CXCR1, CXCR2	NK, DC, M, N, Ba, Plt	CXC
	CXCL6	GCP-2	Granulocyte chemoattractant protein-2	CXCR1, CXCR2	NK, DC, M, N, Ba, Plt	CXC
	CXCL7	NAP-2	Neutrophil activating peptide-2	CXCR2 Duffy	N, M, T, NK Erythrocytes	CXC XC
	CXCL8	IL-8	Interleukin-8	CXCR1, CXCR2	NK, DC, M, N, Ba, Plt	CXC
				Duffy	Erythrocytes	XC
	CXCL9	MIG	Monokine-induced by interferon γ	CXCR3 CCR3 (Antag)	B, T, NK, M, Eo	CXC CC
	CXCL10	IP-10	Interferon γ -inducible protein-10	CXCR3 CCR3 (Antag)	B, T, NK, M, Eo	CXC
	CXCL11	I-TAC	Interferon inducible T cell α chemoattractant	CXCR3 CCR3 (Antag)	B, T, NK, M, Eo	CXC CC
	CXCL12	SDF-1 PBSF	Stromal cell-derived factor 1 Pre-B-cell growth-stimulating factor	CXCR4	SC, B, P, Thy, T, NK, NKT, DC, M, N, Ba, Eo, Plt	CXC
	CXCL13 CXCL14	BCA-1 BRAK	B cell-attracting chemokine-1 Chemokine isolated from breast and kidney tissue	CXCR3, CXCR5	B, T, NK, M, Eo	CXC
	CXCL16	Sexckine		CXCR6	P, T, NKT	CXC
	CC (β)	CCL1	I-309	Inducible 309	CCR8	T, M
CCL2		MCP-1	Monocyte chemoattractant protein-1	CCR1, CCR2, D6	B, T, NKT, DC, M, N, Ba, Eo, Plt	CC
				Duffy	Erythrocytes	XC

Chemokines—cont'd

Class	Systemic name	Chemokine	Receptor(s)	Receptor(s) expressed on	Receptor class
	CCL3	MIP-1 α	Macrophage inflammatory protein 1 α	CCR1, CCR5, CCR9	B, P, Thy, T, NKT,NK, CC
		LD78 α		NKT, NK	
		MIP-1 α S	Macrophage inflammatory protein 1 α S	DC, M, Ba, Eo	
	CCL4	MIP-1 β	Macrophage inflammatory protein 1 β	CCR5, CCR8, D6	B, P, Thy, T, NKT,NK, CC
		LD78 β	CCR1 (Antag)	NKT, NK	
				DC, M, Ba, Eo	
	CCL5	RANTES	Regulated on activation of normal T β cells expressed & secreted	CCR1, CCR3, CCR5, D6	B, P, Thy, T, CC
				NKT, NK	
				DC, M, Ba, Eo	
			Duffy	Erythrocytes	XC
	CCL7	MCP-3	Monocyte chemoattractant protein-3	CCR1, CCR2, CCR3, D6, CCR5 (Antag)	B, P, Thy, T, CC
				NKT, NK	
				DC, M, Ba, Eo	
	CCL8	MCP-2	Monocyte chemoattractant protein-2	CCR1, CCR2, CCR3, CCR5, D6	B, P, Thy, T, NKT,NK, CC
				NKT, NK	
				DC, M, Ba, Eo	
	CCL11	Eotaxin-1		CCR3, CCR5, D6, CCR2 (Antag)	B, P, Thy, T, CC
				CXCR3 (Antag)	NKT, NK, DC, M, N, Ba, Eo, Plt
	CCL13	MCP-4	Monocyte chemoattractant protein-4	CCR1, CCR2, CCR3, D6	B, P, Thy, T, CC
				NKT, DC, M, N,	
	CCL14a	HCC-1	Hemofiltrate CC chemokine-1	CCR1, CCR5, D6	B, T, NKT, CC
				NK, DC, M	
				N, Ba, Eo, Plt	
	CCL14b	HCC-3	Hemofiltrate CC chemokine-3		
	CCL15	HCC-2	Hemofiltrate CC chemokine-2	CCR1, CCR3	B, P, Thy, T, CC
				NKT, DC, M, N,	
				Ba, Eo, Plt	
	CCL16	LKN-1	Leukotactin		
		HCC-4	Hemofiltrate CC chemokine-4	CCR1, CCR2, CCR5, CCR8	B, T, CC
				NKT, NK, DC, M,	
				N, Ba, Eo, Plt	
	CCL17	LEC	Liver-expressed chemokine		
		TARC	Thymus and activation-regulated chemokine	CCR4, CCR8	Thy, T, NKT, CC
	CCL18	DC-CK1	Dendritic cells chemokine-1		
		PARC	Pulmonary and activation-regulated chemokine	CCR7	DC, M, Plt
					B, Thy, T, CC
					NK, DC
	CCL19	ELC	EBV-Induced gene 1 -ligand chemokine	CCR7	B, Thy, T, CC
		MIP-3 β	Macrophage inflammatory protein-3 β	CCX-CKR	NK, DC, M
	CCL20	LARC	Liver & activation-regulated chemokine	CCR6	B, T, NKT, DC
		MIP-3 α	Macrophage inflammatory protein-3 α		
	CCL21	SLC	Secondary lymphoid tissue chemokine	CXCR3	B, Thy, T, CXC
		6Ckine		CCR7	NK, DC, CC
				CCX-CKR	M, Eo
	CCL22	MDC	Macrophage derived chemokine	CCR4	Thy, T, NKT, CC
					DC, Plt

Chemokines—cont'd

Class	Systemic name	Chemokine		Receptor(s)	Receptor(s) expressed on	Receptor class
	CCL23	MPIF-1	Myeloid progenitor inhibitory factor-1	CCR1	B, T, NKT, DC, M, N, BA, Eo, Plt	CC
	CCL24	Eotaxin-2		CCR3	P, Thy, T, Ba, Eo, Plt	CC
	CCL25	TECK	Thymus-expressed chemokine	CCR9 CCX-CKR	P, Thy, T, DC	CC
	CCL26	Eotaxin-3		CCR3	P, Thy, T, Ba, Eo, Plt	CC
	CCL27	CTACK Eskine	Cutaneous T cell-attracting chemokine	CCR10	P, T	CC
	CCL28	MEC		CCR3, CCR10	P, Thy, T, Ba, Eo, Plt	CC
CX ₃ C (γ)	CX3CL1	Fractalkine		CX ₃ CR1	T, NK, M	CX ₃ C
XC (δ)	XCL1	Lymphotactin-α		XCR1	NK	XC
	XCL2	Lymphotactin-β		XCR1	NK	XC

Abbreviations for cells: B, B cells; Ba, Basophils; DC, Dendritic cells; Eo, Eosinophils;M, Macrophages/Monocytes; N, Neutrophils; NK, Natural Killer cells ; NKT, NK T cells; P, plasma cells; Plt, platelets; SC, hematopoietic stem cells; T, T cells.
Other abbreviations: Antag (Antagonist)

Appendix: Cytokines

4

Cytokines

Cytokine	Abbreviation	Receptor	Receptor family	Signaling	Source
Cardiotrophin 1	CT1		Type I (hematopoietin) gp130-utilizing	Jak1, Stat3	myocardial cells
Ciliary neurotrophic factor	CNTF	CNTFR, LIFR	Type I gp130-utilizing	Jak1, Stat3	Schwann cells, astrocytes
Colony stimulating factor 1	CSF1 (M-CSF)	FMS (CSF1R)	receptor tyrosine kinases	Ras/Raf/MAPK	macrophages, endothelium, fibroblasts, other
Colony stimulating factor 2	CSF2 (GM-CSF)	CSF2R	Type I β c utilizing	Jak2, Stat5	T cell, macrophages, endothelium, fibroblasts
Colony stimulating factor 3	CSF3 (G-CSF)	CSF3R	Type I homodimeric	Jak2, Stat3	macrophages, endothelium, fibroblasts, other
Erythropoietin	EPO	EPOR	Type I homodimeric	Jak2, Stat5	kidney, liver
FMS-related tyrosine kinase 3 ligand	FLT3 ligand	FLT3	receptor tyrosine kinases	Ras/Raf/MAPK	diverse tissues
Growth hormone	GH	GHR	Type I homodimeric	Jak2, Stat5b	two GH genes, pituitary, placental
Interferon- α/β	IFN α/β	IFNAR	Type II (interferons) heterodimeric	Jak1, Tyk2, Stat1, Stat2	macrophages, fibroblasts, other
Interferon- γ	IFN γ	IFNGR	Type II heterodimeric	Jak1, Jak2, Stat1	Th1 T cells, NK cells
Interleukin-1 α/β	IL1 α/β	IL1R	IL-1/TLR	IRAK, MyD88, TRAF6, NF- κ B	many cells, especially macrophages
Interleukin-2	IL2	IL2R (TAC, CD25)	Type I γ c-utilizing	Jak1, Jak3, Stat5	T cells
Interleukin-3	IL3	IL3R	Type I β c utilizing	Jak2, Stat5	T cells
Interleukin-4 [#]	IL4 [#]	IL4R	Type I γ c-utilizing	Jak1, Jak3, Stat6	Th2 T cells, mast cells
Interleukin-5	IL5	IL5R	Type I β c utilizing	Jak2, Stat5	Th2 T cells
Interleukin-6	IL6	IL6R	Type I gp130-utilizing	Jak1, Stat3	macrophage, fibroblasts, endothelium, epithelium, T cells, other
Interleukin-7	IL7	IL7R	Type I γ c-utilizing	Jak1, Jak3, Stat5	bone marrow, thymic stromal cells, spleen
Interleukin-9	IL9	IL9R	Type I γ c-utilizing	Jak1, Jak3, Stat5	Th2 T cells
Interleukin-10	IL10	IL10R	Type II heterodimeric	Jak1, Tyk2, Stat3	Th2 T cells, other cells
Interleukin-11	IL11	IL11R	Type I gp130-utilizing	Jak1, Stat3	stromal cells
Interleukin-12	IL12	IL12R	Type I heterodimeric	Jak2, Tyk2, Stat4	macrophages, B cells
Interleukin-13	IL13	IL13R	Type I heterodimeric	Jak1, Tyk2, Stat6	activated T cells
Interleukin-15 [#]	IL15 [#]	IL15R	Type I γ c-utilizing	Jak1, Jak3, Stat5	many cells

Target	Action	Knockout phenotype
myocardium	growth	
neuronal cells	survival	progressive atrophy and loss of motor neurons
committed myelomonocytic progenitors	differentiation, proliferation, survival	monocytopenia, osteopetrosis, female infertility
immature and committed myelomonocytic progenitors, mature macrophages, granulocytes, DC	growth, differentiation, survival, activation	pulmonary alveolar proteinosis
committed progenitors	differentiation, activates mature granulocytes	neutropenia
erythroid precursors	erythroid differentiation	embryonic lethal, severe anemia
Myeloid cells, especially DC	proliferation, differentiation	reduced repopulating hematopoietic stem cells; reduced B cell precursors
diverse tissues	growth, adipocyte differentiation, induces IGF-1	dwarfism*
all NK cells	antiviral, antiproliferative, increased MHC class I activation	susceptibility to viral infections
macrophages, endothelium, NK cells	activation, increased MHC Class II expression, increased antigen presentation	susceptibility to bacterial infections*
CNS, endothelial cells, liver, thymocytes, macrophages	fever, anorexia, activation, acute phase reactants, costimulation, activation, cytokine secretion	
T cells, B cells, NK cells, macrophages	proliferation, cytotoxicity, IFN γ secretion, antibody production	lymphoproliferation*
immature hematopoietic progenitors of multiple lineages	growth, differentiation, survival	no defects in basal hematopoiesis
T cells, B cells, macrophages	proliferation, Th2 differentiation, IgG1 and IgE production, Inhibition of cell-mediated immunity	defective Th2 differentiation and IgE production, Decreased allergic responses
eosinophils, B cells	proliferation, activation	decreased eosinophilia, defective CD5+, B1 cell development
liver, B cells, T cells, thymocytes, myeloid cells, osteoclasts	acute phase reactants, proliferation, differentiation, costimulation	reduced Ig, esp IgA, T lymphopenia, impaired acute phase response
Thymocytes, T cells, B cells	growth, differentiation, survival	SCID*
T cells, mast cell precursors	proliferation	
macrophages	decreased MHC class II expression, decreased antigen presentation	exaggerated inflammatory response and autoimmune disease
hematopoietic stem cells	proliferation	
T cells, NK cells	Th1 differentiation, proliferation, cytotoxicity	defective Th1 differentiation, susceptibility to bacterial infections*
B cells, macrophages	costimulator of proliferation, IgE, increased CD23 and MHC class II, inhibits cytokine secretion and cell-mediated immunity	defective Th2 responses and IgE production, decreased allergic responses
T cells, especially memory cells, NK cells	proliferation, survival	absence of NK and memory cells

Cytokines—cont'd

Cytokine	Abbreviation	Receptor	Receptor family	Signaling	Source
Interleukin-17	IL17	IL17R			Th17 helper cells, cytotoxic T cells
Interleukin-17B	IL17B	IL17R			spinal cord, testis, small intestine
Interleukin-17F	IL17F, ML1				activated CD4 T cells, monocytes, other cells
Interleukin-18	IL18	IL18R	IL-1/TLR	IRAK, MyD88, TRAF6, NF- κ B	
Interleukin-19	IL19		Type I γ c-utilizing	Jak1, Jak3, Stat5	Th2 T cells
Interleukin-20	IL20	IL20R	Type II heterodimeric	Jak1, Tyk2, Stat3	Th2 T cells, other cells
Interleukin-21	IL21	IL21R	Type I gp130-utilizing	Jak1, Stat3	stromal cells
Interleukin-22	IL22	IL22R	Type I heterodimeric	Jak2, Tyk2, Stat4	macrophages, B cells
Interleukin-23	IL23	IL23R	Type I heterodimeric	Jak1, Tyk2, Stat6	activated T cells
Interleukin-24	IL24		Type I γ c-utilizing	Jak1, Jak3, Stat5	many cells
Interleukin-25	IL-25 (IL-17E)	IL17RH1	Type I		various tissues
Interleukin-26	IL26	IL26R	Type II heterodimeric	Stat3	T cells
Interleukin-27	IL27 (IL30/EBI3)	IL27R	Type I gp130-utilizing	Jak1, Stat3	CD4 T cells, NK T cells
Interleukin-28	IL28	IL28R	Type II heterodimeric	Jak1, Stat1	
Interleukin-29	IL29	IL28R	Type II heterodimeric	Jak1, Stat1	
Interleukin-31	IL31	IL31R (GLMR)	Type I gp130-utilizing	Jak1, Stat3, Stat5	
Interleukin-32	IL32				activated T cells, NK cells
Leptin	LEP	LEPR	Type I homodimeric	Jak2, Stat3	adipocytes
Leukemia inhibitory factor	LIF	LIFR	Type I gp130-utilizing	Jak1, Stat3	uterus, macrophage, fibroblasts, endothelium, epithelium, T cells
Lymphotoxin- α	LTA	TNFR	TNF		activated T cells and B cells
Oncostatin M [*]	OSM	OSMR	Type I gp130-utilizing	Jak1, Stat3	macrophage, fibroblasts, endothelium, epithelium, T cells, others
Prolactin	PRL	PRLR	Type I homodimeric	Jak2, Stat5a	two Prl genes pituitary, uterus
Stem cell factor	SCF, c-kit ligand	c-kit	receptor tyrosine kinases	Ras/Raf/MAPK	bone marrow stromal cells
Thrombopoietin	THPO	THPOR	Type I homodimeric	Jak2, Stat5	liver, kidney
Tissue necrosis factor	TNF	TNFR	TNFR	TRAFs, TRADD, FADD, Caspases, NF- κ B	macrophages, T cell
Transforming growth factor β 1, 2, 3	TGFB 1, 2, 3	TGFBR	TGF- β receptor serine kinase family	SMADs, SARA, FAST-1, TAK1	T cells, macrophages, other

*Asterisks denote human disease

#note that two forms of the IL-4 and IL 15 receptor exist

Target	Action	Knockout phenotype
fibroblasts, osteoclasts	T cell activation, osteoclastogenesis	
	induces expression of TGFB, inhibits angiogenesis	
T cells, mast cell precursors	proliferation	
macrophages	decreased MHC class II expression, decreased antigen presentation	exaggerated inflammatory response and autoimmune disease
hematopoietic stem cells	proliferation	
T cells, NK cells	Th1 differentiation, proliferation, cytotoxicity	defective Th1 differentiation, susceptibility to bacterial infections*
B cells, macrophages	costimulator of proliferation, IgE, increased CD23 and MHC class II, inhibits cytokine secretion and cell-mediated immunity	defective Th2 responses and IgE production, decreased allergic responses
T cells, especially memory cells, NK cells	proliferation, survival	absence of NK and memory cells
MHC class II expressing non-T, non-B accessory cells	induction of proinflammatory cytokines	increased susceptibility to experimental autoimmune encephalomyelitis
triggers expansion of naïve CD4 T cells, promotes polarization to Th1	augments IFNG secretion by CD4 T cells to help initiate Th1 differentiation	weak IFNG primary responses, susceptibility to parasitemia
	stimulates production of TNF	
hypothalamus, thyroid	satiety, controls metabolic rate	obesity
embryonic stem cells, neurons, hematopoietic cells	survival	decreased hematopoietic progenitors, defective blastocyst implantation
many cells	cytolysis, lymph node architecture, activation	aberrant lymph node structure
myeloid cells, liver, embryonic stem cells	differentiation, acute phase induction	
mammary epithelium	growth, differentiation	infertility, lactation defects
pluripotent stem cells	activation, growth	defective hematopoietic stem cell proliferation, melanocyte production and germ cell development
committed stem cells, megakaryocytes	platelet	severe thrombocytopenia
neutrophils, macrophages, endothelium, CNS, muscle, fat, many cells	adhesion, activation, adhesion, cytokines, coagulation, fever, cachexia, cytolysis	fever deregulation *
T cells, macrophages, other	inhibits growth and activation

- Immunoreceptor tyrosine-based activation motif (ITAM), 66–67, 211, 213–214, 220
 B-cell receptor, 109
 NK cell receptor, 280
- Immunoreceptor tyrosine-based inhibitory motif (ITIM) 5, 69, 280
- Immunoregulation
 immune complexes, 242
 selective, 1208
- Immunosenescence, 509–510
see also aging
- Immunostimulatory DNA sequences, 297
- Immunosuppression
 acute humoral rejection, 1210
 acute rejection reversal, 1209
 allograft rejection, 1203–1211
 allorecognition interference, 1203–1208
 antilymphocyte antibodies, 1208
 APC function inhibition, 1204
 clinical matrix, 1208–1210
 cytokine reception interference, 1205–1206
 cytokine-stimulated G₁ activation disruption, 1206–1207
 cytoplasmic activation from G₀ to G₁
 interference, 1205
 diabetes mellitus type 1A prevention, 1046–1047
 gene transcription regulatory protein inhibition, 1205
 graft antigen depletion, 1204
 induction, 1208
 leprosy, 394
 long-term maintenance, 1210–1211
 lymphocyte depletion agents, 1207–1208
 malignancy risk, 1410–1411
 multiple sclerosis, 969–970
 nucleoside synthesis de novo inhibitors, 1207
 organ transplantation, 1203–1211
 refractory rejection therapy, 1209–1210
 surface T-cell receptor/co-receptor molecule blockade, 1204–1205
 thymus transplantation, 1255–1256
- Immunosuppressive drugs
 autoimmune hepatitis, 1119
 autoimmune inflammatory syndromes, 907
 bullous pemphigoid, 940
 cicatricial pemphigoid, 944
 idiopathic inflammatory myopathies, 831
 infections, 486–487
 myasthenia gravis treatment, 960
 neutropenia, 928
 pemphigus, 938
 sarcoidosis, 1082–1083
 scleritis, 1092–1093
 systemic sclerosis, 821
- Immunotherapy
 adoptive, 1189–1193
 allergic disease, 1383–1390
- Immunotherapy (*Continued*)
 alternative forms, 1388–1389
 asthma management, 621–622
 atopic dermatitis, 675
 cancer, 1186

 - lymphocyte homing receptors, 291
- Integrin–ICAM interactions, 260
- $\alpha_2\beta_1$ Integrins, 311
- β_2 Integrins, 312, 1461
- mutations, 318
- Interleukin adhesion molecule(s) (ICAMs), leukocyte adhesion, 331, 332
- Interleukin adhesion molecule 1 (ICAM-1), 32, 203
- antihistamine effects, 1320
 - atherosclerosis, 1013, 1014, 1017
 - eosinophil adherence, 362

- Intercellular adhesion molecule 1 (*Continued*)
 Guillain-Barré syndrome, 980
 Hashimoto's thyroiditis, 1029
 LFA-1 interaction, 261
 rheumatoid arthritis, 771
- Intercellular adhesion molecule 2 (ICAM-2),
 eosinophil adherence, 362
- Interferon(s) (IFN), 149–150
 inherited disorders of immunity, 557
 pegylated in cryoglobulinemia treatment, 873
 TLR interface, 746
 type I, 149–150
- Interferon α (IFN- α), 149
 Behçet's disease treatment, 1394
 cancer immunotherapy, 1187–1188
 HBV infection, 1397
 HCV infection, 1397
 Kaposi's sarcoma, 1399
 recurrent respiratory papillomatosis, 1398
 Sjögren's syndrome therapy, 1394
 vasculitis therapy, 1393–1394
- Interferon α and β (IFN- α/β), 118, 1521
 circulating dendritic cells, 495
 inherited disorders of immunity, 557
 viral infections, 422
- Interferon α_{2b} (IFN- α_{2b}), hypereosinophilic
 syndromes, 1396–1397
- Interferon β (IFN- β), 149
 multiple sclerosis treatment, 973, 974, 1393
- Interferon γ (IFN- γ), 22, 149, 1521
 aging, 505
 antibacterial effector function, 404
 atopic dermatitis, 671, 1396
 chronic granulomatous disease treatment,
 336–337, 1401
 HIV infection, 569
 inherited disorders of immunity, 557
 leishmaniasis treatment, 1400
 lepromatous leprosy treatment, 1399
 macrophage activation, 405
 multiple sclerosis, 971
 nontuberculous mycobacterial infection
 treatment, 1400–1401
 osteopetrosis treatment, 1401
 pathway defects, 340–343
 production inhibition by microbial
 components, 398
 pulmonary fibrosis therapy, 1394
 schistosomiasis, 452
 systemic sclerosis treatment, 1394
 T-cell inhibition, 268
 Th1 cells, 262, 263, 264
 differentiation, 265
Toxoplasma gondii infection, 441
 tryptophan degradation, 399
 viral infections, 423
- Interferon γ (IFN- γ) antagonists, Sjögren's
 syndrome, 811
- Interferon γ receptor (IFN- γ R), 149
 deficiencies, 464
 signaling defect, 1457
- Interferon γ receptor 1 (IFN- γ R1), 341
 deficiencies
 complete, 341, 343, 553–554
 dominant negative, 342–343
 hematopoietic stem cell transplantation, 1248
- Interferon γ receptor 1 (*Continued*)
 partial, 342
 partial dominant/recessive, 555
- Interferon γ receptor 2 (IFN- γ R2) deficiency,
 554–555
 partial recessive, 555
- Interleukin 1 (IL-1), 19, 21, 1521
 functions, 164–165
 gene family, 164
 juvenile idiopathic arthritis, 795
 myasthenia gravis thymus, 958
 ocular disease, 1086
 phagocyte recruitment, 404
 rheumatoid arthritis, 777
 signaling, 165
 spondyloarthritis susceptibility, 843
- Interleukin 1 receptor (IL-1R), 164
- Interleukin 1 receptor (IL-1R) antagonists, 165, 650
 juvenile idiopathic arthritis, 799
 rheumatoid arthritis, 785, 1413
- Interleukin 1 receptor-associated kinase 1
 (IRAK1), 42–43, 165
- Interleukin 1 receptor-associated kinase 4
 (IRAK4), 42–43
 deficiency, 464, 465, 559
- Interleukin 1 (IL-1)/Toll-like receptor family,
 164–165
- Interleukin 2 (IL-2), 146–147, 1521
 cancer immunotherapy, 1187–1189
 clinical uses, 147
 common variable immunodeficiency
 treatment, 1401
 HIV therapy, 1398, 1399
 lepromatous leprosy treatment, 1399
 malignancy, 282
 T-cell inhibition, 268
 Treg maintenance, 253
- Interleukin 2 receptor (IL-2R), 403
 IL-15, 147–148
 receptor tyrosine kinases, 1349
 signaling deficiencies, 212
 X-linked SCID, 535–536, 1286, 1288
- Interleukin 2 receptor (IL-2R) inhibitors 1414
- Interleukin 3 (IL-3), 19, 21, 22, 145–146, 1521
 eosinophil receptors, 363
 eosinophil synthesized, 364
 eosinophilopoiesis, 361
- Interleukin 4 (IL-4), 21–22, 26, 147, 1521
 asthma, 601, 621
 immunologic occupational, 730
 therapy, 1394, 1396
 atopic dermatitis, 671
 basophils, 349
 clinical uses, 147
 eosinophil degranulation, 364–365
 eosinophil synthesized, 364
 helminth parasite production, 451, 452
 inhibitory activity, 1395
 production by Th2 cells, 264
 signaling blockade, 1395
 Th2 differentiation, 265
 Th2 immunity, 190
- Interleukin 4 receptors (IL-4R), 147
- Interleukin 5 (IL-5), 146, 1521
 asthma, 601, 1396
 immunologic occupational, 730
- Interleukin 5 (*Continued*)
 atopic dermatitis, 671
 treatment, 1396
 eosinophil activation in nasal polyps, 635
 eosinophil receptors, 363
 eosinophilopoiesis, 361
 hypereosinophilic syndrome treatment, 1397
 production by Th2 cells, 264
 ulcerative colitis, 1111
- Interleukin 6 (IL-6), 21, 22, 140, 145, 1521
 juvenile idiopathic arthritis, 795, 799
 myasthenia gravis thymus, 958
 rheumatoid arthritis, 777
 viral infections, 423
- Interleukin 6 receptor (IL-6R), 140
